Chapter 1. Introduction

1.1. Scope of this manual

The User's Guide for Toolkit Developers provides detailed information about the design of Geant4 classes as well as the information required to extend the current functionality of the Geant4 toolkit. This manual is designed to:

• provide a repository of information for those who want to understand or refer to the detailed design of the toolkit, and
• provide details and procedures for extending the functionality of the toolkit so that experienced users may contribute code which is consistent with the overall design of Geant4.

This manual is intended for developers and experienced users of Geant4. It is assumed that the reader is already familiar with functionality of the Geant4 toolkit as explained in the "User's Guide For Application Developers", and also has a working knowledge of programming using C++. A knowledge of object-oriented analysis and design will also be useful in understanding this manual. It is also useful to consult the "Software Reference Manual" which provides a list of Geant4 classes and their major methods.

Detailed discussions of the physics included in Geant4 are provided in the "Physics Reference Manual".

1.2. How to use this manual

Part I: to understand the goal of the software design of Geant4, it is useful to begin by reading the User Requirements Document referred to in the next section.

Part II: "Design and Function of the Geant4 Categories" provides detailed information about the design of each class category and the classes in it. Before considering an extension of one of the toolkit categories, a detailed understanding of that category is required.

Part III: "Extending Toolkit Functionality" explains in some detail how to extend the functionality of Geant4. Most of the class categories are covered and some, which are especially useful to most users, are covered in greater detail.

It is not necessary to understand the entire manual before adding a new functionality. To add a new physics process, for example, only the following items must be read and understood:

• the design principle described in the "Physics processes" chapter of Part II
• techniques explained in the "Physics processes" chapter of Part III.

1.3. User Requirements Document

At the beginning of Geant4 development, a set of user requirements was collected in order to inform the object-oriented analysis and design of the toolkit. The User Requirements Document follows the PSS-05 software engineering standards and is available at

This document provides a general description of the main capabilities and constraints of the toolkit. It also defines three types of users characterized by their level of interaction with the system. Specific requirements are also listed and classified.

[Status of this chapter]

Chapter 2. Design and Function of Geant4
Categories

2.1. Introduction

Geant4 exploits advanced software engineering techniques based on the Booch/UML Object Oriented Methodology and follows the evolution of the ESA Software Engineering Standards for the development process. The "spiral", or iterative, approach has been adopted. User requirements were collected in the initial phase and problem domain decomposition, object-oriented methods, and CASE tools were used for analysis and design. This produced a clear hierarchical structure of sub-domains linked by a uni-directional flow of dependencies. This led to a software product which is modular and flexible (a toolkit) and in which the physics implementation is transparent and open to user validation of physics predictions. It allows the user to understand, customize and extend the toolkit in all domains. At the same time the modular architecture allows the user to load only needed components.

2.2. Run

2.2.1. Design Philosophy

The run category manages collections of events that share a common beam and detector implementation.

2.2.2. Class Design

• **G4Run** - This class represents a run. An object of this class is constructed and deleted by G4RunManager.
• **G4RunManager** - the run controller class. Users must register detector construction, physics list and primary generator action classes to it. G4RunManager or a derived class must be a singleton.
• **G4RunManagerKernel** - provides control of the Geant4 kernel. This class is constructed by G4RunManager.

[Status of this chapter]

28.06.05 - under construction
December 2006 - Converted from latex to Docbook by K. Amako

2.3. Event

2.3.1. Design Philosophy

In high energy physics the primary unit of an experimental run is an event. An event consists of a set of primary particles produced in an interaction, and a set of detector responses to these particles.

In Geant4, objects of the G4Event class are the primary units of a simulation run. Before the event is processed, it contains primary vertices and primary particles produced by an external physics generator. After the event is processed, it may also contain hits, digitizations ,and optionally, trajectories generated by the simulation. The event category manages events and provides an abstract interface to external physics generators.

G4Event and its content vertices and particles are independent of other classes. This isolation allows Geant4-based simulation programs to be independent of specific choices for physics generators and of specific solutions for storing the "Monte Carlo truth". G4Event avoids keeping any transient information which is not meaningful after event processing is complete. Thus the user can store objects of this class for processing further down the program chain. For performance reasons, G4Event and its content classes are not persistent. Instead the user must provide the transient-to-persistent conversion.

2.3.2. Class Design

• **G4Event** - This class represents an event. It is constructed and deleted by G4RunManager or its derived class.
• **G4EventManager** - This class controls an event. It must be a singleton and should be constructed by G4RunManager.

• **G4VPrimaryGenerator** - the abstract base class of all of primary generators. This class has only one pure virtual method, GeneratePrimaryVertex(), which takes a G4Event object, generates a primary vertex and associates primary particles with the vertex.

Booch diagrams for classes related to the event and event generator classes are shown in Figure 2.1 and Figure 2.2.

**2.4. Tracking**

The tracking category manages the contribution of the processes to the evolution of a track's state and provides information in sensitive volumes for hits and digitization.
2.4.1. Design Philosophy

It is well known that the overall performance of a detector simulation depends critically on the CPU time spent propagating the particle through one step. The most important consideration in the object design of the tracking category is maintaining high execution speed in the Geant4 simulation while utilizing the power of the object-oriented approach.

An extreme approach to the particle tracking design would be to integrate all functionalities required for the propagation of a particle into a single class. This design approach looks object-oriented because a particle in the real world propagates by itself while interacting with the material surrounding it. However, in terms of data hiding, which is one of the most important ingredients in the object-oriented approach, the design can be improved.

Combining all the necessary functionalities into a single class exposes all the data attributes to a large number of methods in the class. This is basically equivalent to using a common block in Fortran.

Instead of the 'big-class' approach, a hierarchical design was employed by Geant4. The hierarchical approach, which includes inheritance and aggregation, enables large, complex software systems to be designed in a structured way. The simulation of a particle passing through matter is a complex task involving particles, detector geometry, physics interactions and hits in the detector. It is well-suited to the hierarchical approach. The hierarchical design manages the complexity of the tracking category by separating the system into layers. Each layer may then be designed independently of the others.

In order to maintain high-performance tracking, use of the inheritance ('is-a' relation) hierarchy in the tracking category was avoided as much as possible. For example, track and particle classes might have been designed so that a track is a particle. In this scheme, however, whenever a track object is used, time is spent copying the data from the particle object into the track object. Adopting the aggregation ('has-a' relation) hierarchy requires only pointers to be copied, thus providing a performance advantage.

2.4.2. Class Design

Figure 2.3 shows a general overview of the tracking design in Unified Modelling Language Notation.

Figure 2.3. Tracking design
Design and Function of Geant4 Categories

- **G4TrackingManager** is an interface between the event and track categories and the tracking category. It handles the message passing between the upper hierarchical object, which is the event manager (G4EventManager), and lower hierarchical objects in the tracking category. G4TrackingManager is responsible for processing one track which it receives from the event manager.

  G4TrackingManager aggregates the pointers to G4SteppingManager, G4Trajectory and G4UserTrackingAction. It also has a 'use' relation to G4Track.

- **G4SteppingManager** plays an essential role in particle tracking. It performs message passing to objects in all categories related to particle transport, such as geometry and physics processes. Its public method Stepping() steers the stepping of the particle. The algorithm employed in this method is basically the same as that in Geant3. The Geant4 implementation, however, relies on the inheritance hierarchy of the physics interactions. The hierarchical design of the physics interactions enables the stepping manager to handle them as abstract objects. Hence, the manager is not concerned with concrete interaction objects such as bremsstrahlung or pair creation. The actual invocations of various interactions during the stepping are done through a dynamic binding mechanism. This mechanism shields the tracking category from any change in the design of the physics process classes, including the addition or subtraction of new processes.

  G4SteppingManager also aggregates
  - the pointers to G4Navigator from the geometry category, to the current G4Track, and
  - the list of secondaries from the current track (through a G4TrackVector) to G4UserSteppingAction and to G4VSteppingVerbose.

  It also has a 'use' relation to G4ProcessManager and G4ParticleChange in the physics processes class category.

- **G4Track** - the class G4Track represents a particle which is pushed by G4SteppingManager. It holds information required for stepping a particle, for example, the current position, the time since the start of stepping, the identification of the geometrical volume which contains the particle, etc. Dynamic information, such as particle momentum and energy, is held in the class through a pointer to the G4DynamicParticle class. Static information, such as the particle mass and charge is stored in the G4DynamicParticle class through the pointer to the G4ParticleDefinition class. Here the aggregation hierarchical design is extensively employed to maintain high tracking performance.

- **G4TrajectoryPoint and G4Trajectory** - the class G4TrajectoryPoint holds the state of the particle after propagating one step. Among other things, it includes information on space-time, energy-momentum and geometrical volumes.

  G4Trajectory aggregates all G4TrajectoryPoint objects which belong to the particle being propagated. G4TrackingManager takes care of adding the G4TrajectoryPoint to a G4Trajectory object if the user requested it (see Geant4 User's Guide - For Application Developers. The life of a G4Trajectory object spans an event, contrary to G4Track objects, which are deleted from memory after being processed.

- **G4UserTrackingAction and G4UserSteppingAction** - G4UserTrackingAction is a base class from which user actions at the beginning or end of tracking may be derived. Similarly, G4UserSteppingAction is a base class from which user actions at the beginning or end of each step may be derived.

### 2.4.3. Tracking Algorithm

The key classes for tracking in Geant4 are G4TrackingManager and G4SteppingManager. The singleton object "TrackingManager" from G4TrackingManager keeps all information related to a particular track, and it also manages all actions necessary to complete the tracking. The tracking proceeds by pushing a particle by a step, the length of which is defined by one of the active processes. The "TrackingManager" object delegates management of each of the steps to the "SteppingManager" object. This object keeps all information related to a particular step.

The public method ProcessOneTrack() in G4TrackingManager is the key to managing the tracking, while the public method Stepping() is the key to managing one step. The algorithms used in these methods are explained below.

**ProcessOneTrack() in G4TrackingManager**

1. Actions before tracking the particle: Clear secondary particle vector
2. Pre tracking user intervention process.
3. Construct a trajectory if it is requested
4. Give SteppingManager the pointer to the track which will be tracked
5. Inform beginning of tracking to physics processes
6. Track the particle Step-by-Step while it is alive  
   • Call Stepping method of G4SteppingManager  
   • Append a trajectory point to the trajectory object if it is requested
7. Post tracking user intervention process.
8. Destroy the trajectory if it was created

Stepping() in G4SteppingManager

1. Initialize current step
2. If particle is stopped, get the minimum life time from all the at rest processes and invoke InvokeAtRestDoItProc for the selected AtRest processes
3. If particle is not stopped:
   • Invoke DefinePhysicalStepLength, that finds the minimum step length demanded by the active processes  
   • Invoke InvokeAlongStepDoItProc  
   • Update current track properties by taking into account all changes by AlongStepDoIt  
   • Update the safety  
   • Invoke PostStepDoIt of the active discrete process.  
   • Update the track length  
   • Send G4Step information to Hit/Dig if the volume is sensitive  
   • Invoke the user intervention process.  
   • Return the value of the StepStatus.

2.4.4. Interaction with Physics Processes

The interaction of the tracking category with the physics processes is done in two ways. First each process can limit
the step length through one of its three GetPhysicalInteractionLength() methods, AtRest, AlongStep,
or PostStep. Second, for the selected processes the DoIt (AtRest, AlongStep or PostStep) methods are invoked.
All this interaction is managed by the Stepping method of G4SteppingManager. To calculate the step length,
the DefinePhysicalStepLength() method is called. The flow of this method is the following:

• Obtain maximum allowed Step in the volume define by the user through G4UserLimits.
• The PostStepGetPhysicalInteractionLength of all active processes is called. Each process returns a step length
and the minimum one is chosen. This method also returns a G4ForceCondition flag, to indicate if the process
is forced or not:
   • Forced : Corresponding PostStepDoIt is forced.
   • NotForced : Corresponding PostStepDoIt is not forced unless this process limits the step.
   • Conditionally : Only when AlongStepDoIt limits the step, corresponding PoststepDoIt is invoked.
   • ExclusivelyForced : Corresponding PostStepDoIt is exclusively forced.
   All other DoIt including AlongStepDoIts are ignored.
• The AlongStepGetPhysicalInteractionLength method of all active processes is called. Each process returns a
step length and the minimum of these is chosen. This method also returns a fGPILSelection flag, to indicate if
the process is the selected one can be is forced or not:
   • CandidateForSelection: this process can be the winner. If its step length is the smallest, it will be the process
defining the step (the process
   • NotCandidateForSelection: this process cannot be the winner. Even if its step length is taken as the smallest,
it will not be the process defining the step

The method G4SteppingManager::InvokeAlongStepDoIts() is in charge of calling the AlongStepDoIt methods of the different processes:

• If the current step is defined by a 'ExclusivelyForced' PostStepGetPhysicalInteractionLength, no AlongStepDoIt
method will be invoked
• Else, all the active continuous processes will be invoked, and they return the ParticleChange. After it for each
process the following is executed:
   • Update the G4Step information by using final state information of the track given by a physics process. This
is done through the UpdateStepForAlongStep method of the ParticleChange
• Then for each secondary:
  • It is checked if its kinetic energy is smaller than the energy threshold for the material. In this case the particle is assigned a 0. kinetic energy and its energy is added as deposited energy of the parent track. This check is only done if the flag ApplyCutFlag is set for the particle (by default it is set to 'false' for all particles, user may change it in its G4VUserPhysicsList). If the track has the flag IsGoodForTracking 'true' this check will have no effect (used mainly to track particles below threshold)
  • The parentID and the process pointer which created this track are set
  • The secondary track is added to the list of secondaries. If it has 0. kinetic energy, it is only added if it it invokes a rest process at the beginning of the tracking
  • The track status is set according to what the process defined

The method G4SteppingManager::InvokePostStepDoIts is on charge of calling the PostStepDoIt methods of the different processes.

• Invoke the PostStepDoIt methods of the specified discrete process (the one selected by the PostStepGetPhysicalInteractionLength, and they return the ParticleChange. The order of invocation of processes is inverse to the order used for the GPIL methods. After it for each process the following is executed:
  • Update PostStepPoint of Step according to ParticleChange
  • Update G4Track according to ParticleChange after each PostStepDoIt
  • Update safety after each invocation of PostStepDoIts
  • The secondaries from ParticleChange are stored to SecondaryList
  • Then for each secondary:
    • It is checked if its kinetic energy is smaller than the energy threshold for the material. In this case the particle is assigned a 0. kinetic energy and its energy is added as deposited energy of the parent track. This check is only done if the flag ApplyCutFlag is set for the particle (by default it is set to 'false' for all particles, user may change it in its G4VUserPhysicsList). If the track has the flag IsGoodForTracking 'true' this check will have no effect (used mainly to track particles below threshold)
    • The parentID and the process pointer which created this track are set
    • The secondary track is added to the list of secondaries. If it has 0. kinetic energy, it is only added if it it invokes a rest process at the beginning of the tracking
    • The track status is set according to what the process defined

The method G4SteppingManager::InvokeAtRestDoIts is called instead of the three above methods in case the track status is fStopAndALive. It is on charge of selecting the rest process which has the shortest time before and then invoke it:

• To select the process with shortest tiem, the AtRestGPIL method of all active processes is called. Each process returns a lifetime and the minimum one is chosen. This method return also a G4ForceCondition flag, to indicate if the process is forced or not: = Forced : Corresponding AtRestDoIt is forced. = NotForced : Corresponding AtRestDoIt is not forced unless this process limits the step.
• Set the step length of current track and step to 0.
• Invoke the AtRestDoIt methods of the specified at rest process, and they return the ParticleChange. The order of invocation of processes is inverse to the order used for the GPIL methods.

After it for each process the following is executed:
• Set the current process as a process which defined this Step length.
• Update the G4Step information by using final state information of the track given by a physics process. This is done through the UpdateStepForAtRest method of the ParticleChange.
• The secondaries from ParticleChange are stored to SecondaryList
• Then for each secondary:
  • It is checked if its kinetic energy is smaller than the energy threshold for the material. In this case the particle is assigned a 0. kinetic energy and its energy is added as deposited energy of the parent track. This check is only done if the flag ApplyCutFlag is set for the particle (by default it is set to 'false' for all particles, user may change it in its G4VUserPhysicsList). If the track has the flag IsGoodForTracking 'true' this check will have no effect (used mainly to track particles below threshold)
  • The parentID and the process pointer which created this track are set
  • The secondary track is added to the list of secondaries. If it has 0. kinetic energy, it is only added if it it invokes a rest process at the beginning of the tracking
  • The track is updated and its status is set according to what the process defined
2.4.5. Ordering of Methods of Physics Processes

The ProcessManager of a particle is responsible for providing the correct ordering of process invocations. G4SteppingManager invokes the processes at each phase just following the order given by the ProcessManager of the corresponding particle.

For some processes the order is important. Geant4 provides by default the right ordering. It is always possible for the user to choose the order of process invocations at the initial set up phase of Geant4. This default ordering is the following:

1. Ordering of GetPhysicalInteractionLength
   - In the loop of GetPhysicalInteractionLength of AlongStepDoIt, the Transportation process has to be invoked at the end.
   - In the loop of GetPhysicalInteractionLength of AlongStepDoIt, the Multiple Scattering process has to be invoked just before the Transportation process.

2. Ordering of DoIts
   - There is only some special cases. For example, the Cherenkov process needs the energy loss information of the current step for its DoIt invocation. Therefore, the EnergyLoss process has to be invoked before the Cherenkov process. This ordering is provided by the process manager. Energy loss information necessary for the Cherenkov process is passed using G4Step (or the static dE/dX table is used together with the step length information in G4Step to obtain the energy loss information). Any other?

2.5. Physics Processes

2.5.1. Design Philosophy

The processes category contains the implementations of particle transportation and physical interactions. All physics process conform to the basic interface G4VProcess, but different approaches have been developed for the detailed design of each sub-category.

For the decay sub-category, the decays of all long-lived, unstable particles are handled by a single process. This process gets the step length from the mean life of the particle. The generation of decay products requires a knowledge of the branching ratios and/or data distributions stored in the particle class.

The electromagnetic sub-category is divided further into the following packages:

- **standard**: handling basic properties for electron, positron, photon and hadron interactions,
- **low energy**: providing alternative models extended down to lower energies than the standard package,
- **muons**: handling muon interactions,
- **x-rays**: providing specific code for x-ray physics,
- **optical**: providing specific code for optical photons,
- **utils**: collecting utility classes used by the above packages.

It provides the features of openness and extensibility resulting from the use of object-oriented technology; alternative physics models, obeying the same process abstract interface, are often available for a given type of interaction.

For hadronic physics, an additional set of implementation frameworks was added to accommodate the large number of possible modeling approaches. The top-level framework provides the basic interface to other Geant4 categories. It satisfies the most general use-case for hadronic shower simulations, namely to provide inclusive cross sections and final state generation. The frameworks are then refined for increasingly specific use-cases, building a hierarchy in which each level implements the interface specified by the level above it. A given hadronic process.
may be implemented at any one of these levels. For example, the process may be implemented by one of several models, and each of the models may in turn be implemented by several sub-models at the lower framework levels.

2.5.2. Class Design

2.5.2.1. General

The object-oriented design of the generic physics process G4VProcess and its relation to the process manager is shown in Figure 2.4. Figure 2.5 shows how specific physics processes are related to G4VProcess.

2.6. Hits and Digitization

2.6.1. Design Philosophy

In Geant4 a *hit* is a snapshot of a physical interaction or an accumulation of interactions of a track or tracks in a "sensitive" detector component. A digitization, or *digit*, represents a detector output, such as an ADC/TDC count or a trigger signal. A *digit* is created from one or more hits and/or other *digits*. 
Given the wide variety of Geant4 applications, ways of describing detector sensitivity and the quantities to be stored in the hits and digits vary greatly. This category therefore provides only abstract classes for both detector sensitivity and hits/digits. It also provides tools for organizing the hits/digits into collections.

### 2.6.2. Class Design

- **G4SensitiveDetectorManager** - a list of G4SensitiveDetectors.
- **G4HitsStructure** - a tree-like structure of G4Hit collections. Each branch represents the hits in a given sub-detector. For example, the first level of branches may consist of a tracker, ECAL, and HCAL, while the second level, in HCAL, consists of the barrel and endcaps. Finally, the barrel may have phi-slices, Z-slices, etc.
- **G4SensitiveDetector** - an abstract class of all sensitive volumes.
- **G4HitsCollection** - a collection of hits. Instantiates an RWCollection class.
- **G4VHit** - this class has all the information about a particular hit caused by a single step.
- **G4Digitizer** - the class of objects which transform the hits deposited by particles into digitizations.
- **G4DigitizerManager** - the (single) object dispatching common messages to individual digitizers.
- **G4Digit** - an abstract (base) class for all G4 digitizations. This could be data as simple as a single byte, or as complex as an Ntuple.
- **G4DigitStructure** - digitizations are organized as a structure, which could be anything between a single value and an Ntuple.

The object-oriented design of the 'hit' related classes is shown in the following class diagrams. The diagrams are described in the Booch notation. Figure 2.6 shows the general management of hit classes. Figure 2.7 shows the OO design of user-related hit classes. Figure 2.8 shows the OO design of the readout geometry.
2.7. Geometry

2.7.1. Design Philosophy

The geometry category provides the ability to describe a geometrical structure and propagate particles efficiently through it. This is done in part with the aid of two central concepts, the logical and physical volumes. A logical volume represents a detector element of a given shape which may contain other volumes, and which may have other attributes. It has access to other information which is independent of its physical location in the detector, such as material and sensitive detector behavior. A physical volume represents the spatial positioning or placement of the logical volume with respect to an enclosing mother (logical) volume. Thus a hierarchical tree structure of volumes can be built with each volume containing smaller volumes (which may not overlap). Repetitive structures can be represented by specialized physical volumes, such as replicas and parameterized placements, sometimes resulting in a large savings in memory.

In Geant4 the logical volume has been refined by defining the shape as a separate entity, called a solid. Solids with simple shapes, like rectilinear boxes, trapezoids, spherical or cylindrical sections or shells, each have their properties coded separately, in accord with the concept of Constructed Solid Geometry (CSG). More complex solids are defined by their bounding surfaces, which can be planes, second-order surfaces or higher-order B-spline surfaces, and belong to the Boundary Representations (BREP) sub-category.

Another way to build solids is by boolean combination - union, intersection and subtraction. The elemental solids should be CSGs.

Although a detector is naturally and best described as a hierarchy of volumes, efficiency is not critically dependent on this. An optimization technique, called voxelization, allows efficient navigation even in ``flat” geometries, typical of those produced by CAD systems.

2.7.2. Class Design

- **G4GeometryManager** - responsible for managing ``high level” objects in the geometry subdomain, notably including opening and closing (“locking”) the geometry, and creating/deleting optimization information for G4Navigator. The class is a "singleton”.
- **G4LogicalVolumeStore** - a container for optionally storing created logical volumes. It enables traversal of all logical volumes by the UI/user/etc.
• **G4LogicalVolume** - represents a leaf node or unpositioned subtree in the geometry hierarchy. It may have daughters ascribed to it, and is also responsible for retrieval of the physical and tracking attributes of the physical volume that it represents. These attributes include solid, material, magnetic field, and optionally user limits, sensitive detectors, etc. Logical volumes are optionally entered into the G4LogicalVolumeStore.

• **G4MagneticField** - a class responsible for the magnetic field in each volume, including the calculation of particle trajectories along curved paths. In cases where the geometry step limits the particle's step, the distance calculated is guaranteed to be the distance to a volume boundary.

• **G4Navigator** - a class used by the tracking management, able to obtain/calculate tracking-time geometrical information such as distance to the next volume, or to find the physical volume containing a given point in the world reference system. The navigator maintains a transformation history and other information used to optimize the tracking time performance.

• **G4NavigationHistory** - responsible for maintenance of the history of the path taken through the geometrical hierarchy. It is principally a utility class for use by G4Navigator.

• **G4NormalNavigation** - a utility class for navigation in volumes containing only G4PVPlacement daughter volumes.

• **G4ParameterisedNavigation** - a utility class for navigation in volumes containing a single G4PVParameterised volume for which voxels for the replicated volumes have been constructed.

• **G4VoxelNavigation** - a utility class for navigation in volumes containing only G4PVPlacement daughter volumes for which voxels have been constructed.

• **G4PhysicalVolumeStore** - a container for optionally storing created physical volumes. It enables traversal of all physical volumes by the UI/user/etc. All solids should be registered with G4PhysicalVolumeStore, and removed on their destruction. It is intended principally for the UI browser.

• **G4PVPlacement** - a physical volume corresponding to a single touchable detector element, positioned within and relative to a mother volume.

• **G4PVIndexed** - a volume able to perform simple changes to its shape (corresponds to GSPOSP), and representing a single touchable detector element.

• **G4PVReplica** - a physical volume representing many identically formed touchable detector elements, differing only in their positioning. The elements' positions are determined by means of a simple formula, and the elements completely fill the containing mother volume.

• **G4PVParameterised** - a physical volume representing many touchable detector elements differing in their positioning and dimensions. Both are calculated by means of a G4PVParameterisation object. Each element's position is calculated as per G4PVReplica, and each element's shape can be modified by means of a user supplied formula.

• **G4PVParameterisation** - a parameterisation class able to compute the transformation and, indirectly, the dimensions of parameterised volumes, given a replication number.

• **G4SmartVoxelProxy** - a class for proxying smart voxels. The class represents either a header (in turn referring to more VoxelProxies) or a node. If created as a node, calls to GetHeader cause an exception, and likewise GetNode when a header.

• **G4SmartVoxelHeader** - represents a single axis of virtual division. Contains the individual divisions which are potentially further divided along different axes.

• **G4SmartVoxelNode** - a single virtual division, containing the physical volumes inside its boundaries and those of its parents.

• **G4VoxelLimits** - represents limitation/restrictions of space, where restrictions are only made perpendicular to the cartesian axes.

• **G4RotationMatrixStore** - a container for optionally storing created G4RotationMatrices.

• **G4SolidStore** - a container for optionally storing created solids. It enables traversal of all/any solids by the UI/user/etc. The class is a "singleton".

• **G4Solid** - position independent geometrical entities. They have only 'shape', and encompass both CSG and boundary representations. They are optionally entered into the G4SolidStore. This class defines, but does not implement, functions to compute distances to/from the shape. Functions are also defined to check whether a point is inside the shape, to return the surface normal of the shape at a given point, and to compute the extent of the shape.

• **G4VSweptSolid** - a solid created by performing a 3D transformation on a finite planar face.

• **G4HalfSpaceSolid** - a solid created by the boolean AND of one or more half space surfaces.
• **G4BREPSolid** - a solid created by an arbitrary set of finite surfaces.

• **G4VTouchable** - a class that maintains a "reference" on a given touchable element of the detector - a kind of bookmark. It enables a given detector element to be saved during tracking (in case of booleans/user code/etc.) and the corresponding G4PhysicalVolume retrieved later, with its "state" information (path through the tree) optionally restored so that navigation can be restarted. G4Touchables provide fast access to the transformation from the global reference system to that of the saved detector element.

• **G4TouchableHistory** - object representing a touchable detector element, and its history in the geometrical hierarchy, including its net resultant local-to-global transform.

• **G4GRSSolid** - object representing a touchable solid. It maintains the association between a solid and its net resultant local-to-global transform.

• **G4GRSVolume** - object representing a touchable detector element. It maintains associations between a physical volume and its net resultant local-to-global transform.

• **G4TransformStore** - a container for optionally storing created G4AffineTransform objects. It is responsible for storing and providing access to transformations that are constant at tracking time.

• **G4AffineTransform** - a class for geometric affine transformations. It supports efficient arbitrary rotation and transformation of vectors and the computation of compound and inverse transformations. A "rotation flag" is maintained internally for greater computational efficiency for transforms that do not involve rotation.

• **G4UserLimits** - responsible for user limits on step size, ascribable to individual volumes.

Figure 2.9 shows a general overview, in UML notation, of the geometry design. A detailed collection of class diagrams from the geometry category is found in the Appendix.

![Diagram of Geometry Design](image)

**Figure 2.9. Overview of the geometry**

### 2.7.3. Additional Geometry Diagrams

Additional diagrams for the object-oriented design of the 'geometry' related classes are included here. Figure 2.10 shows the class diagram for smart voxels. Figure 2.11 shows the class diagram for the navigator.
2.8. Electromagnetic Fields

The object-oriented design of the classes related to the electromagnetic field is shown in the class diagram of Figure 2.12. The diagram is described in UML notation.
2.9. Particles

2.9.1. Design Philosophy

The particles category implements the facilities necessary to describe the physical properties of particles for the simulation of particle-matter interactions. All particles are based on the G4ParticleDefinition class, which describes basic properties such as mass, charge, etc., and also allows the particle to carry a list of processes to which it is sensitive. A first-level extension of this class defines the interface for particles that carry cuts information, for example range cut versus energy cut equivalence. A set of virtual, intermediate classes for leptons, bosons, mesons, baryons, etc., allows the implementation of concrete particle classes which define the actual particle properties and, in particular, implement the actual range versus energy cuts equivalence. All concrete particle classes are instantiated as singletons to ensure that all physics processes refer to the same particle properties.

2.9.2. Class Design

The object-oriented design of the 'particles' related classes is shown in the following class diagrams. The diagrams are described in the Booch notation. Figure 2.13 shows a general overview of the particle classes. Figure 2.14 shows classes related to the particle table. Figure 2.15 shows the classes related to the particle decay table.

Figure 2.13. Particle classes
2.10. Materials

2.10.1. Design Philosophy

The design of the materials category reflects what exists in nature: materials are made of a single element or a mixture of elements, and elements are made of a single isotope or a mixture of isotopes. Because the physical properties of materials can be described in a generic way by quantities which can be specified directly, such as density, or derived from the element composition, only concrete classes are necessary in this category.

The material category implements the facilities necessary to describe the physical properties of materials for the simulation of particle-matter interactions. Characteristics like radiation and interaction length, excitation energy loss, coefficients in the Bethe-Bloch formula, shell correction factors, etc., are computed from the element, and if necessary, the isotope composition.

The material category also implements facilities to describe surface properties used in the tracking of optical photons.
2.10.2. Class Design

The object-oriented design of the 'materials' related classes is shown in the class diagram: Figure 2.16. The diagram is described in the Booch notation.

Figure 2.16.

2.11. Global Usage

2.11.1. Design Philosophy

The global category covers the system of units, constants, numerics and random number handling. It can be considered a place-holder for "general purpose" classes used by all categories defined in Geant4. No back-dependencies to other Geant4 categories affect the "global" domain. There are direct dependencies of the global category on external packages, such as CLHEP, STL, and miscellaneous system utilities.

Within the management sub-category are "utility" classes generally used within the Geant4 kernel. They are, for the most part, uncorrelated with one another and include:

- G4Allocator
- G4FastVector
- G4ReferenceCountedHandle
- G4PhysicsVector, G4LPhysicsFreeVector, G4PhysicsOrderedFreeVector
- G4Timer
- G4UserLimits
- G4UnitsTable

A general description of these classes is given in section 3.2 of the Geant4 User's Guide for Application Developers.
In applications where it is necessary to generate random numbers (normally from the same engine) in many different methods and parts of the program, it is highly desirable not to rely on or require knowledge of the global objects instantiated. By using static methods via a unique generator, the randomness of a sequence of numbers is best assured. Hence the use of a static generator has been introduced in the original design of HEPRandom as a project requirement in Geant4.

2.11.2. Class Design

Analysis and design of the HEPRandom module have been achieved following the Booch Object-Oriented methodology. Some of the original design diagrams in Booch notation are reported below. Figure 2.17 is a general picture of the static class diagram.

- **HepRandomEngine** - abstract class defining the interface for each Random engine. Its pure virtual methods must be defined by its subclasses representing the concrete Random engines.
- **HepJamesRandom** - class inheriting from HepRandomEngine and defining a flat random number generator according to the algorithm described in "F.James, Comp.Phys.Comm. 60 (1990) 329". This class is instantiated by default as the default random engine.
- **DRand48Engine** - class inheriting from HepRandomEngine and defining a flat random number generator according to the drand48() and srand48() system functions from the C standard library.
- **RandEngine** - class inheriting from HepRandomEngine and defining a flat random number generator according to the rand() and srand() system functions from the C standard library.
- **RanluxEngine** - class inheriting from HepRandomEngine and defining a flat random number generator according to the algorithm described in "F.James, Comp.Phys.Comm. 60 (1990) 329-344" and originally implemented in FORTRAN 77 as part of the MATHLIB HEP library. It provides 5 different "luxury" levels [0..4].
- **RanecuEngine** - class inheriting from HepRandomEngine and defining a flat random number generator according to the algorithm RANECU originally written in FORTRAN 77 as part of the MATHLIB HEP library. It uses a table of seeds which provides uncorrelated couples of seed values.
- **HepRandom** - the main class collecting all the methods defining the different random generators applied to HepRandomEngine. It is a singleton class which all the distribution classes derive from. This singleton is instantiated by default.
- **RandFlat** - distribution class for flat random number generation. It also provides methods to fill an array of flat random values, given its size or shoot bits.
- **RandExponential** - distribution class defining exponential random number distribution, given a mean. It also provides a method to fill an array of flat random values, given its size.
- **RandGauss** - distribution class defining Gauss random number distribution, given a mean or specifying also a deviation. It also provides a method to fill an array of flat random values, given its size.
- **RandBreitWigner** - distribution class defining the Breit-Wigner random number distribution. It also provides a method to fill an array of flat random values, given its size.
- **RandPoisson** - distribution class defining Poisson random number distribution, given a mean. It also provides a method to fill an array of flat random values, given its size.
Figure 2.17. HEPRandom module

Figure 2.18 is a dynamic object diagram illustrating the situation when a single random number is thrown by the static generator according to one of the available distributions. Only one engine is assumed to active at a time.

Figure 2.18. Shooting via the generator

Figure 2.19 illustrates a random number being thrown by explicitly specifying an engine which can be shared by many distribution objects. The static interface is skipped here.
Figure 2.19. Shooting via distribution objects

Figure 2.20 illustrates the situation when many generators are defined, each by a distribution and an engine. The static interface is skipped here.

Figure 2.20. Shooting with arbitrary engines

Informations written in this manual are extracted from the original manifesto distributed with the HEPRandom package (http://cern.ch/clhep/manual/UserGuide/Random/Random.html).

HEPNumerics

The HEPNumerics module includes a set of classes which implement numerical algorithms for general use in Geant4. The User's Guide for Application Developers contains a description of each class. Most of the algorithms were implemented using methods from the following books:

HEPGeometry

### 2.12. Visualisation

#### 2.12.1. Design Philosophy

The visualisation category consists of the classes required to display detector geometry, particle trajectories, tracking steps, and hits. It also provides visualisation drivers, which are interfaces to external graphics systems.

A wide variety of user requirements went into the design of the visualisation category, for example:

- very quick response in surveying successive events,
- high-quality output for presentation and documentation,
- flexible camera control for debugging detector geometry and physics,
- selection of visualisable objects,
- interactive picking of graphical objects for attribute editing or feedback to the associated data,
- highlighting incorrect intersections of physical volumes,
- co-working with graphical user interfaces.

Because it is very difficult to respond to all of these requirements with only one built-in visualiser, an abstract interface was developed which supports several complementary graphics systems. Here the term *graphics system* means either an application running as a process independent of Geant4 or a graphics library to be compiled with Geant4. A concrete implementation of the interface is called a *visualisation driver*, which can use a graphics library directly, communicate with an independent process via pipe or socket, or simply write an intermediate file for a separate viewer.

#### 2.12.2. The Graphics Interfaces

- **G4VVisManager**: All user code writes to the graphics systems through this pure abstract interface. It contains Draw methods for all the graphics primitives in the graphics_reps category (G4Polyline, G4Circle, etc.), geometry objects (through their base classes, G4VSolid, G4PhysicalVolume and G4LogicalVolume) and hits and trajectories (through their base classes, G4VHit and G4VTrajectory).

  Since this is an abstract interface, all user code must check that there exists a concrete instantiation of it. A static method is provided, so a typical user code fragment is:

  ```c++
  G4VVisManager* pVVisManager = G4VVisManager::GetConcreteInstance();
  if(pVVisManager) {
    pVVisManager->Draw(G4Circle... ...
  }
  ``

  Note that this allows the building an application without a concrete implementation, for example for a batch job, even if some code, like the above, is still included. Most of the novice examples can be built this way if G4VIS_NONE is specified.

  The concrete implementation of this interface is hereafter referred to as the **visualisation manager**.

- **G4VGraphicsScene**: The visualisation manager must also provide a concrete implementation of the subsidiary interface, G4VGraphicsScene. It is only for use by the kernel and the modeling category. It offers direct access to a "scene handler" through a reference provided by the visualisation manager. It is described in more detail in the section on extending the toolkit functionality.

The Geant4 distribution includes implementations of the above interfaces, namely **G4VisManager** and **G4VSceneHandler** respectively, and their associated classes. These define further abstract base classes for visualisation drivers. Together they form the **Geant4 Visualisation System**. A variety of concrete visualisation drivers are also included in the distribution. Details of how to implement a visualisation driver are given in Section 3.6. Of course, it is always possible for a user to implement his or her own concrete implementations of G4VVisManager and G4VGraphicsScene replacing the Geant4 Visualisation System altogether.

#### 2.12.3. The Geant4 Visualisation System

The Geant4 Visualisation System consists of
Design and Function of Geant4 Categories

- **G4VisManager**: An implementation of the G4VVisManager interface. It manages multiple graphics systems and defines three more concepts -- the scene (G4Scene), the scene handler (base class G4VSceneHandler, itself a sub-class of G4VGraphicsScene) and the viewer (base class G4VViewer) -- see below. G4VisManager is a singleton and an abstract class, requiring the user to derive from it a concrete visualisation manager (G4VisExecutive is provided -- see below). Roles and structure of the visualisation manager are described in Chapter 8 of the User's Guide for Application Developers.

- **G4VisExecutive**: A concrete visualisation manager that implements the virtual functions RegisterGraphicsSystems and RegisterModelFactories. These functions must be in the users' domain, since the graphics systems and models that are instantiated by them are, in many cases, provided by the user (graphics libraries, etc.). It is therefore implemented as a .hh-.icc combination that is designed to be included in the users' code. Of course, the user may write his or her own.

- **G4Scene** The scene is a list if models for physical volumes, axes, hits, trajectories, etc. - see Section Section 2.12.4. They are distinguished according to their lifetime -- `run-duration" for physical volumes, etc., `end-of-event" for hits and trajectories, etc. The end-of-event models are only to be used when the Geant4 state indicates the end of event has been reached. The scene has an extent (G4VisExtent), which is updated by the scene when a new model is added (each model itself has an extent), and a `standard' target point; these are used to define the standard view -- see below. In addition, the scene keeps flags which indicate whether end-of-event objects should be accumulated or refreshed for each event or run.

- **G4VGraphicsSystem**: This is an abstract base class for scene handler and viewer factories. It is used by the visualisation manager to create scene handlers and viewers on request.

- **G4VSceneHandler**: A sub-class of G4VGraphicsScene, itself an abstract base class for specific scene handlers, whose job is to convert the scene into graphics-system-specific code for the viewer. For example, the scene handler may create a graphical database, taking care to separate run-duration (persistent) and end-of-event (transient) information (this is described further in Section 3.6.1.6.

- **G4VViewer**: An abstract base class for specific viewers. Its job is to create windows or files and identify where and how the final view should be rendered. It has view parameters (G4ViewParameters) which specify viewpoint direction, type of rendering (wireframe or surface), etc. It is the view's responsibility, noting the scene's extent and target point, to choose a camera position and magnification that ensures that the scene is automatically and comfortably rendered in the viewing window. This is then the standard view, and any further operations requested by the user - zoom, pan, etc. - are relative to this standard view. The class G4ViewParameters has utility routines to assist this procedure; it is strongly advised that toolkit developers writing a viewer should study the G4ViewParameters class, whose header file contains much useful information (also preserved in the Software Reference Manual).

The viewer is messaged by the vis manager when the user issues commands, such as /vis/viewer/refresh. This invokes methods such as SetView, ClearView and DrawView. A detailed description of the call sequences is given in Section 3.6.1.2- Section 3.6.1.5.

Note there is no restriction on the number or type of scene handlers or viewers. There may be several scene handlers processing the same or different scenes, each with several viewers (for example, the same scene from differing viewpoints).

By defining a set of three C++ classes inheriting from the virtual base classes - G4VGraphicsSystem, G4VSceneHandler and G4VViewer - an arbitrary graphics system can easily be plugged in to Geant4. The plugged-in graphics system is then available for visualising detector simulations. Together, this set of three concrete classes is called a "visualisation driver". The DAWN-File driver, for example, is the interface to the Fukui Renderer DAWN, and is implemented by the following set of classes:

1. G4DAWNFILE : public G4VGraphicsSystem for creation of the scene handlers and viewers
2. G4DAWNFILESceneHandler : public G4VSceneHandler for modeling 3D scenes
3. G4DAWNFILEView : public G4VView for rendering 3D scenes

Several visualisation drivers are distributed with Geant4. They are complementary to each other in many aspects. For details, see Chapter 8 of the User's Guide for Application Developers.

### 2.12.4. Modeling sub-category

- **G4VModel** - a base class for visualisation models. A model is a graphics-system-independent description of a Geant4 component.
The sub-category visualisation/modeling defines how to model a 3D scene for visualisation. The term "3D scene" indicates a set of visualisable component objects put in a 3D world. A concrete class inheriting from the abstract base class G4VModel defines a "model", which describes how to visualise the corresponding component object belonging to a 3D scene. G4ModelingParameters defines various associated parameters.

For example, G4PhysicalVolumeModel knows how to visualise a physical volume. It describes a physical volume and its daughters to any desired depth. G4HitsModel knows how to visualise hits. G4TrajectoriesModel knows how to visualise trajectories.

The main task of a model is to describe itself to a 3D scene by giving a concrete implementation of the following virtual method of G4VModel:

\[
\text{virtual void DescribeYourselfTo (G4VGraphicsScene&) = 0;}
\]

The argument class G4VGraphicsScene is a minimal abstract interface of a 3D scene for the Geant4 kernel defined in the graphics_reps category. Since G4VSceneHandler and its concrete descendants inherit from G4VGraphicsScene, the method DescribeYourselfTo() can pass information of a 3D scene to a visualisation driver.

It is easy for a toolkit developer of Geant4 to add a new kind of visualisable component object. It is done by implementing a new class inheriting from G4VModel.

- **G4VTrajectoryModel** - an abstract base class for trajectory drawing models.

A trajectory model governs how an individual trajectory is drawn. Concrete models inheriting from G4VTrajectoryModel must implement two pure virtual functions:

\[
\begin{align*}
\text{virtual void Draw(const G4VTrajectory&, G4int i_mode = 0) const = 0;} \\
\text{virtual void Print(std::ostream& ostr) const = 0;}
\end{align*}
\]

See for example G4TrajectoryDrawByParticleID.

- **G4VModelFactory** - an abstract base class for factories creating models and associated messengers.

It is not necessary to generate messengers for a trajectory model that will be constructed and configured directly in compiled code. If the user requires model creation and configuration features through interactive commands, however, there must be a mechanism to generate both models and their associated messengers. This is the role of G4VModelFactory. Concrete factories inheriting from G4VModelFactory are responsible for creating a concrete model and concrete messengers. To help ensure a type safe messenger to model interaction on the command line, the messengers should inherit from G4VModelCommand.

Concrete factories must implement one pure virtual function:

\[
\text{virtual ModelAndMessengers Create(const G4String& placement, const G4String& modelName) = 0;}
\]

where placement indicates which directory space the commands should occupy. See for example G4TrajectoryDrawByParticleIDFactory.

### 2.12.5. View parameters

View parameters such as camera parameters, drawing styles (wireframe/surface etc) are held by G4ViewParameters. Each viewer holds a view parameters object which can be changed interactively and a default object (for use in the /vis/viewer/reset command).

If a toolkit developer of Geant4 wants to add entries of view parameters, he should add fields and methods to G4ViewParameters.
2.12.6. Visualisation Attributes

All drawable objects (should) have a method:

```cpp
const G4VisAttributes* GetVisAttributes() const;
```

A drawable object might be:

- a "visible" (i.e., inheriting G4Visible), such as a polyhedron, polyline, circle, etc. (note that text is a slightly special case - see below) or
- a solid whose vis attributes are held in its logical volume.

2.12.6.1. Finding the applicable vis attributes

This is an issue for all scene handlers. The scene handler is where the colour, style, auxiliary edge visibility, marker size, etc., of individual drawable objects are needed.

2.12.6.1.1. Visibles

If the vis attributes pointer is zero, drivers should pick up the default vis attributes from the viewer:

```cpp
const G4VisAttributes* pVisAtts = visible.GetVisAttributes();
if (!pVisAtts)
    pVisAtts = fpViewer->GetViewParameters().GetDefaultVisAttributes();
```

where `visible` denotes any visible object (polyhedron, circle, etc.).

There is a utility function `G4VViewer::GetApplicableVisAttributes` which does this, so an alternative is:

```cpp
const G4VisAttributes* pVisAtts =
    fpViewer->GetApplicableVisAttributes(visible.GetVisAttributes());
```

Confusingly, there is a utility function `G4VSceneHandler::GetColour` which also does this, so if it’s only colour you need, the following suffices:

```cpp
const G4Colour& colour = pVisAtts->GetColour();
```

but equally well:

```cpp
const G4VisAttributes* pVisAtts =
    fpViewer->GetApplicableVisAttributes(visible.GetVisAttributes());
const G4Colour& colour = pVisAtts->GetColour();
```

or even:

```cpp
const G4VisAttributes* pVisAtts = visible.GetVisAttributes();
if (!pVisAtts)
    pVisAtts = fpViewer->GetViewParameters().GetDefaultVisAttributes();
const G4Colour& colour = pVisAtts->GetColour();
```

2.12.6.1.2. Text

Text is a special case because it has its own default vis attributes:

```cpp
const G4VisAttributes* pVisAtts = text.GetVisAttributes();
if (!pVisAtts)
    pVisAtts = fpViewer->GetViewParameters().GetDefaultTextVisAttributes();
const G4Colour& colour = pVisAtts->GetColour();
```
and there is a utility function G4VSceneHandler::GetTextColour:

```c++
const G4Colour& colour GetTextColour(text);
```

### 2.12.6.1.3. Solids

For specific solids, the G4PhysicalVolumeModel that provides the solids also provides, via PreAddSolid, a pointer to its vis attributes. If the vis attributes pointer in the logical volume is zero, it provides a pointer to the default vis attributes in the model, which in turn is (currently) provided by the viewer's vis attributes (see G4VSceneHandler::CreateModelingParameters). So the vis attributes pointer is guaranteed to be pertinent.

If the concrete driver does not implement AddSolid for any particular solid, the base class converts it to primitives (usually a G4Polyhedron) and again, the vis attributes pointer is guaranteed.

### 2.12.6.1.4. Drawing style

The drawing style is normally determined by the view parameters but for individual drawable objects it may be overridden by the forced drawing style flags in the vis attributes. A utility function G4ViewParameters::DrawingStyle G4VSceneHandler::GetDrawingStyle is provided:

```c++
G4ViewParameters::DrawingStyle drawing_style = GetDrawingStyle(pVisAtts);
```

### 2.12.6.1.5. Auxiliary edges

Similarly, the visibility of auxiliary/soft edges is normally determined by the view parameters but may be overridden by the forced auxiliary edge visible flag in the vis attributes. Again, a utility function G4VSceneHandler::GetAuxEdgeVisible is provided:

```c++
G4bool isAuxEdgeVisible = GetAuxEdgeVisible (pVisAtts);
```

### 2.12.6.1.6. LineSegmentsPerCircle

Also, the precision of rendering curved edges in the polyhedral representation of volumes is normally determined by the view parameters but may be overridden by a forced attribute. A utility function that respects this, G4VSceneHandler::GetNoOfSides, is provided. For example:

```c++
G4Polyhedron::SetNumberOfRotationSteps (GetNoOfSides (pVisAttribs));
```

### 2.12.6.1.7. Marker size

These have nothing to do with vis attributes; they are an extra property of markers, i.e., objects that inherit G4VMarker (circles, squares, text, etc.). However, the algorithm for the actual size is quite complicated and a utility function G4VSceneHandler::GetMarkerSize is provided:

```c++
MarkerSizeType sizeType;
G4double size = GetMarkerSize (text, sizeType);
```

sizeType is world or screen, signifying that the size is in world coordinates or screen coordinates respectively.

2.13. Intercoms

2.13.1. Design Philosophy

The intercoms category implements an expandable command interpreter which is the key mechanism in Geant4 for realizing customizable and state-dependent user interactions with all categories without being perturbed by the dependencies among classes. The capturing of commands is handled by a C++ abstract class G4UISession. Various concrete implementations of the command capturer are contained in the [user] interfaces category. Taking into account the rapid evolution of graphical user interface (GUI) technology and consequent dependence on external facilities, plural and extensible GUIs are offered.

Programmers need only know how to register the commands and parameters appropriate to their problem domain; no knowledge of GUI programming is required to allow an application to use them through one of the available GUIs.

The intercoms category also provides the virtual base classes

- G4VVisManager,
- G4VGraphicsScene, and
- G4VGlobalFastSimulationManager.

2.13.2. Class Design

- G4UISession
- G4UIBatch
- G4UICommand
- G4UIParameter
- G4UImessenger
- G4UIExecutive: A concrete interface manager. It will register the UI selected by the environment variable set. It will take first by default the following order: G4UI_USE_QT, G4UI_USE_XM, G4UI_USE_WIN32, G4UI_USE_TCSH, Terminal

The object-oriented design of the 'user interface' related classes is shown in the class diagram Figure 2.21. The diagram is described in the Booch notation.

2.14. Parallelism in Geant4: multi-threading capabilities

2.14.1. Event level parallelism

Geant4 event-level parallelism is based on a master-worker model in which a set of threads (the workers) are spawned and are responsible for the simulation of the events, while the steering and control of the simulation is given to an additional entity (the master).

Multithreading functionalities are implemented with new classes or modification to existing classes in the run category:

- The new run-manager class `G4MTRunManager` (that inherits from `G4RunManager`) implements the master model. It uses the mandatory class `G4MTRunManagerKernel`, a multi-threaded equivalent of `G4RunManagerKernel`.
- The new run-manager class `G4WorkerRunManager` (that inherits from `G4WorkerRunManager`) implements the worker model. It uses the mandatory class `G4WorkerRunManagerKernel`, the worker equivalent of `G4RunManagerKernel`.
- The new user-initialization class `G4VUserActionInitialization` is responsible for the instantiation of thread-local user actions.
- The new user-initialization class `G4UserWorkerInitialization` is responsible for the initialization of worker threads.

Additional information on Geant4 multi-threading model can be found in the next section.

In this chapter, after a brief reminder of basic design choices, we will concentrate on aspects that are important for kernel developers, in particular we will discuss the most critical aspect for multi-threading in Geant4: memory handling, split-classes and thread-local storage. In the following it is assumed that the user is already familiar with general aspects of multi-threading. The section Additional Material contains resources to additional information.

2.14.2. General Design

Geant4 Version 10.0 introduces parallelism at the event level: events are tracked concurrently by independent threads. The parallelism model is master-worker in which one or more threads are responsible of performing the simulation, while a separate control flow controls and steers the work. A diagram of the general overview of a multi-threaded Geant4 application is shown here:

![Diagram of Geant4 multi-threaded application](image)

Figure 2.22. Simplified schema of the master-worker model employed in Geant4
The user interacts with the master that is responsible of creating and controlling worker threads. Before the simulation is started per-event seeds are generated by the master. This operation guarantees reproducibility. Once thread are spawned and configured, each worker is responsible of creating a new G4Run and for simulating a subset of the events. At the end of the run the results from each run are merged into the global run. Details on how to interact with a multi-threaded simulation are discussed in the Guide for Application Developers”.

Geant4 parallelization makes use of POSIX standard. The use of this standard in Geant4 guarantees maximum portability between system and integration with advanced parallelization frameworks (for example we have verified this model co-works with TBB and MPI).

To effectively reduce the memory consumption in a multi-threaded application, workers share instances of objects that consume the majority of memory (geometry and physics tables); workers own thread-private instances of the other classes (e.g. SensiticeDetectors, hits, etc). This choice allowed the design of a lock-free code (i.e. no use of mutex during the event loop), this guarantees maximum scalability (cfr: Euro-Par2010, Part II LNCS6272, pp.287-303). Thread safety is obtained via Thread Local Storage.

In a similar way to the sequential version of Geant4, master and workers are represented by instances of classes inheriting from G4RunManager: the G4MTRunManager class represents the master model, while G4WorkerRunManager instances represent worker models. The user is responsible of instantiating a single G4MTRunManager (or derived user-class) instance. This class will instantiate and control one or more G4WorkerRunManager instances. User should never instantiate directly an instance of G4WorkerRunManager class.

A simplified class-diagram of the relevant classes for multi-threading and their relationship is shown here:

![Figure 2.23. Relevant classes and their interaction for multi-threaded applications](image)

As in sequential Geant4 user interacts with Geant4 kernel via user-initializations and user-actions. User initializations (G4VUserDetectorConstruction, GVUserPhysicsList and the new G4VUserActionInitialization) instances are shared among all threads (as such they are registered to the G4MTRunManager instance); while user actions (G4VUserPrimaryGeneratorAction, G4UserRunAction, G4UserSteppingAction and G4UserTrackingAction) are not shared and a separate instance exists for each thread. Since the master does not perform simulation of events user actions do not have functions for G4MTRunManager and should not be assigned to it. G4RunAction is the exception to this rule since it can be attached to the master G4MTRunManager to allow for merging of partial results produced by workers.

### 2.14.3. Memory handling in Geant4 Version 10.0

#### 2.14.3.1. Introduction

In Geant4 we distinguish two broad types of classes: ones whose instances are separate for each thread (such as a physics process, which has a state), and ones whose instances are shared between threads (e.g. an element G4Element which holds constant data).

In a few cases classes exist which have a mixed behavior - part of their state is constant, and part is per-worker. A simple example of this is a particle definitions, such as G4Electron, which holds both data (which is constant) and a pointer to the G4ProcessManager object for electrons - which must be different for each worker (thread).

We handle these 'split' classes specially, to enable data members and methods which correspond to the per-thread state to give a different result on each worker thread. The implementation of this requires an array for each worker
(thread) and an additional indirection - which imposes a cost for each time the method is called. However this overhead is small and has been measured to be about 1%. In this section we will discuss the details of how we achieve thread-safety for different use-cases. The information contained here is of particular relevance for toolkit developers that need to adapt code to multi-threading to increase performances (typically to reduce the memory footprint of an application sharing between threads memory consuming objects). It is however of general interest to understand some of the more delicate aspects of multi-threading.

2.14.3.2. Thread safety and sharing of objects

To better understand how memory is handled and what are the issues introduced by multi-threading it is easier to proceed with a simplified example.

Let us consider the simplest possible class `G4Class` that consists of a single data member:

```c++
class G4Class {
    [static] G4double fValue; //static keyword is optional
};
```

Our goal is to transform the code of `G4Class` to make it thread-safe. A class (or better, a method of a class) is thread-safe if more than one thread can simultaneously operate on the class data member or its methods without interfering with each other in an unpredictable way. For example if two threads concurrently write and read the value of the data field `fValue` and this data field is shared among threads, the two threads can interfere with each other if no special code to synchronize the thread is added. This condition is called data-race and is particular dangerous and difficult to debug.

A classical way to solve the data-race problem is to protect the critical section of the code and the concurrent access to a shared memory location using a lock or a mutex (see section Threading model utilities and functions). However this technique can reduce overall performances because only one thread at a time is allowed to be executed. It is important to reduce at the minimum the use of locks and mutexes, especially in the event loop. In Geant4 we have achieved thread-safety via the use of thread local storage. This allow for a virtually lock-free code at the price of an increased memory footprint and a small CPU penalty. For an explanation of what is thread local storage several external resources exists, for a very simple introduction, but adequate for our discussion, web resources give enough details (e.g. wikipedia).

Before going into the details of how to use thread-local-storage mechanism we need to introduce some terminology.

We define an instance of a variable thread-local(or thread-private) if each thread owns a copy of the variable. A thread-shared variable, on the contrary, is an instance of a variable that is shared among the threads (i.e. all thread have access to the same memory location holding the value of the variable). If we need to share the same memory location containing the value of `fValue` between several instances of `G4Class` we call the data field instance-shared otherwise (the majority of the cases) it is instance-local. These definition are an over-simplification that does not take into account pointers and sharing/ownership of the pointee, however the issues that we will discuss in the following can be extended to the case of pointers and the (shared) pointee.

It is clear that, for the case of thread-shared variables, all thread needs synchronization to avoid data-race conditions (it is worthwhile to remind that there are no race conditions if the variable is accessed only to be read, for example in the case the variable is marked as `const`.

One or more instances of `G4Class` can exist at the same time in our application. These instances can be thread-local (e.g. `G4VProcess`) or thread-shared (e.g. `G4LogicalVolume`). In addition the class data field `fValue` can be by itself thread-local or thread-shared. The actions to be taken to transform the code depend on three key aspects:

- Do we need to make the instance(s) of `G4Class` thread-local or thread-shared?
- Do we need to make the data field `fValue` thread-local or thread-shared?
- In case more than one instance of `G4Class` exists at the same time, do we need `fValue` to be instance-local or instance-shared?

This gives rise to 8 different possible combinations, summarized in the following figures, each one discussed in detail in the following.
2.14.3.2.1. Case A: thread-local class instance(s), thread-shared and instance-shared data field

In this case each thread has its own instance(s) of type `G4Class`. We need to share `fValue` both among threads and among instances. As for a sequential application, we can simply add the `static` keyword to the declaration of `fValue`. This technique is common in Geant4 but has the disadvantage that the result code is thread-unsafe (unless locks are used). Trying to add `const` or modify its value (with the use of a lock) only outside of the event loop is the simplest and best solution:

```cpp
class G4Class {
    static const G4double fValue;
};
```

2.14.3.2.2. Case B: thread-local class instance(s), thread-local and instance-shared data field.

This scenario is also common in Geant4; we need to share a variable (e.g., a data table) between instances of the same class. However, it is impractical or it would lead to wrong results if we share among threads `fValue` (i.e., the penalty due to the need of locks is high or the data field holds event-dependent information). To make the code thread-safe we mark the data field thread-local via the keyword `G4ThreadLocal`.

---

</tbody>
</table>
It should be noted that only simple data types can be declared `G4ThreadLocal`. More information and the procedures to make an object instance thread-safe via thread-local-storage are explained in this web-page.

### 2.14.3.2.3. Case C: thread-local class instance(s), thread-shared and instance-local data field

A possible use-case is the need to reduce the application memory footprint, providing a component to the thread-local instances of `G4Class` that is shared among threads (e.g. a large cross-section data table that is different for each instance). Since this scenario strongly depends on the implementation details it is not possible to define a common strategy that guarantees thread-safety. The best one being to try to make this shared component `const`.

### 2.14.3.2.4. Case D: thread-local class instance(s), thread-local and instance-local data field

This case is the simplest, nothing has to be changed in the original code.

### 2.14.3.2.5. Case E: thread-shared class instance(s), thread-shared and instance-shared data field

For what thread-safety is concerned this case is equivalent to Case A, and the same recommendations and comments hold.

### 2.14.3.2.6. Case F: thread-shared class instance(s), thread-local and instance-shared data field

For what thread-safety is concerned this case is equivalent to Case B, and the same recommendations and comments hold.

### 2.14.3.2.7. Case G: thread-shared class instance(s), thread-shared and instance-shared data field

Since the class instances are shared among threads the data field are automatically thread-shared. No action is needed, however access to data field is, in general thread unsafe, and the same comments and recommendations done for Case A are valid.

### 2.14.3.2.8. Case H: thread-shared class instance(s), thread-local and instance-local data field

This is the most complex case and it is relatively common in Geant4 Version 10.0. For example `G4ParticleDefinition` instances are shared among the threads, but the `G4ProcessManager` pointer data field needs to be thread and instance local. To obtain thread-safe code two possible solutions exists:

- Use the split-class mechanism. This requires some deep understanding of Geant4 multi-threading and coordination with the kernel developers. Split-classes result in thread-safe code with good CPU performances, however they also require modification in other aspects of kernel category (in particular they require changes in run category). The idea behind the split-class mechanism is that each thread-shared instance of `G4Class` initializes the thread-local data fields `copying` the initial status from the equivalent instance of the master, that is guaranteed to be fully configured. Additional details on split classes are available in a dedicated section
- If performances are not a concern a simpler solution is available. This is a simplified version of the split-class mechanism that does not copy the initial status of the thread-local data field from the master thread. A typical example is a `cache` variable that reduces CPU usage storing in memory the value of a CPU intensive calculation for several events. In such a case the `G4Cache` utility class can be employed (see `G4Cache`).

```cpp
#include "G4Types.hh"
class G4Class {
  static G4ThreadLocal G4double fValue;
};
```
2.14.3.3. Details on the split classes mechanism

We will here describe the split-class mechanism, central in Geant4 multi-threading, developing a thread-safe split-class starting from our simplified example of G4Class. It will be clear that this technique allows for minimal changes of public API of the classes and thus is very suitable to make thread-safe code without breaking back-compatibility.

To better describe the changes we introduce a setter and a getter in the sequential version of our class (e.g. before migration to multi-threading):

```cpp
class G4Class {
private:
    G4double fValue;
public:
    G4Class() {  }
    void SetMyData( G4double aValue ) { fValue = aValue; }
    G4double GetMyData() const { return fValue; }
};
```

Instances of this class will be shared among threads (because it is a memory consuming objects) and we want to transform this class to a split-class.

As a first step we add to the declaration of fValue the TLS keyword `G4ThreadLocal` (in a POSIX system, is a typedef to `__thread`). Unfortunately there are several constraints on what can be specified as TLS. In particular the data member has to be declared static (or being a global variable):

```cpp
#include "tls.hh"
class G4Class {
private:
    static G4ThreadLocal G4double fValue;
public:
    G4Class() {  }
    void SetMyData( G4double aValue ) { fValue = aValue; }
    G4double GetMyData() const { return fValue; }
};
G4ThreadLocal G4double G4Class::fValue = -1;
```

The problem occurs if we need more than one instance of type G4Class with a instance-local different value of fValue. How to obtain this behavior now that we have declared the data member as static? The method used to solve this problem is called split class mechanism. The idea is to collect all thread-local data fields into a new separate class, instances of which (one per original instance of G4Class) are organized in an array. This array is accessed via a index representing a unique identifier of a given class instance.

We can modify the code as follow:

```cpp
class G4ClassData {
public:
    G4double fValue;
    void initialize() {
        fValue = -1;
    }
};
typedef G4Splitter>G4ClassData< G4ClassManager;
typedef G4ClassManager G4ClassSubInstanceManager;
#define G4MT_fValue ((subInstanceManager.offset[gClassInstanceId]).fValue)
class G4Class {
private:
    G4int gClassInstanceId;
    static G4ClassSubInstanceManager subInstanceManager;
public:
    G4Class()
```
As one can see the use of the value of \textit{fValue} variable is very similar to how we use it in the original sequential mode, all the handling of the TLS is done in the template class \textit{G4Splitter} that can be implemented as:

Let's consider a function that can be called concurrently by more than one thread:

We expect that each thread will write on screen: "0.1 0.2"

When we declare the variable \textit{a}, the static object \textit{subInstanceManager} in memory has the state:
The constructor of G4Class calls `CreateSubInstance`, and since at this point `totalobj` equals 1, `G4Splitter::NewSubInstances` is called. This will create a buffer of 512 pointers of type `G4ClassData`, each of them is initialized (via `G4ClassData::initialize`) to the value -1. Finally, `G4Splitter::CreateSubInstance` returns 0 and `a.gClassInstanceId` equals 0. When `a.SetMyData(0.1)` is called, the call is equivalent to:

```
subInstanceManager.offset[0].fValue = 0.1;
```

When now we declare the instance `b` the procedure is repeated, except that, since `totalobj` now equals 1 and `workertotalspace` is 512, there is no need to call `G4Splitter::NewSubInstances` and we use the next available array position in `offset`. Only if we create more than 512 instances of `G4Class` memory array is reallocated with more space for the new `G4ClassData` instances.

Since `offset` and `workertotalspace` are marked `G4ThreadLocal` this mechanism allows each thread to have its own copy of `fValue`. The function `foo()` can be called from different threads and they will use the thread-shared `a` and `b` to access a thread-local `fValue` data field. No data-race condition occurs and there is no need of mutexes and locks.

An additional complication is that if the initialization of the thread-local part is not trivial and we want to copy some values from the corresponding values of the master thread (in our example, how to initialize `fValue` to a value that depends on the run condition?). The initial status of the thread-local data field must be initialized, for each worker, in a controlled way. The run category classes must be modified to prepare the TLS space of each thread before any work is being performed.

The following diagram shows the chain of calls in `G4ParticleDefinition` when a thread needs to access a process pointer:

![Diagram](image.png)

**Figure 2.25. Simplified view of the split-class mechanism**

### 2.14.3.3.1. List of split-classes

In Geant4 Version 10.0 the following are split-classes:

- For geometry related split classes the class `G4GeomSplitter` implements the split-class mechanism. These are the geometry-related split-classes:
  - `G4LogicalVolume`
  - `G4PhysicalVolume`
  - `G4PVReplica`
  - `G4Region`
  - `G4PloyconeSide`
  - `G4PolyhedraSide`

- For Physics related split-classes the classes `G4DefSplitter` and `G4VUPLSplitter` implement the split-class mechanism. These are the physics-related split-classes:
  - `G4ParticleDefinition`
  - `G4VUserPhysicsList`
  - `G4VModularPhysicsList`
  - `G4VPhysicsConstructor`
2.14.3.4. Explicit memory handling

In the following some utility classes and functions to help memory handling are discussed. Before going in the detail it should be noted that all of these utilities have a (small) CPU and memory performance penalty, they should be used with caution and only if other simpler methods are not possible. In some cases limitations are present.

2.14.3.4.1. The template class G4Cache

In many cases this is not needed the full functionality of split-classes and what we really want are independent thread-local and instance-local data field in thread-shared instances of G4Class. A concrete example being a class representing a cross-section that is made shared because of its memory footprint. It requires a data field to act as a cache to store a value of a CPU intensive calculation. Since different thread share this instance we need to transform the code in a manner similar to what we do for split-classes mechanism. The helper class G4Cache can be used for this purpose (note that the complication of the initial value of the thread-local data field is not present in this case).

G4Cache is a template class that implements a light-weight split-classes mechanism. Being a template it allows for storing any user-defined type. The public API of this class is very simple and it provides two methods

```cpp
T& G4Cache<T>::Get() const;
void G4Cache<T>::Put(const T& val) const;
```

to access a thread-local instance of the cached object. For example:

```cpp
#include "G4Cache.hh"
class G4Class {
  G4Cache>G4double fValue;
  void foo() {
    // Store a thread-local value
    G4double val = someHeavyCalc();
    fValue.Put(val);
  }
  void bar() {
    // Get a thread-local value:
    G4double local = fValue.Get();
  }
};
```

Since Get returns a reference to the cached object is possible to avoid to use Put to update the cache:

```cpp
void G4Class::bar() {
  // Get a reference to the thread-local value:
  G4double &local = fValue.Get();
  // Use local as in the original sequential code, cache is updated, without the need to use Put
  local++;
}
```

In case the cache holds an instance of an object it is possible to implement lazy initialization, as in the following example:

```cpp
#include "G4Cache.hh"
class G4Class {
  G4Cache>G4Something* fValue;
  void bar() {
    // Get a thread-local value:
    G4Something* local = fValue.Get();
    if ( local == 0 ) {
      local = new G4Something( ... );
      // warning: this may cause a memory leak. Use of G4AutoDelete can help, see later
    }
  }
};
```

Since the use of G4Cache implies some CPU penalty, it is a good practice to try to minimize its use. For example, do not use single G4Cache for several data fields, instead use a helper structure as the template parameter for G4Cache:
Two specialized versions of G4Cache exist that implement the semantics of std::vector and std::map

- **G4VectorCache<T>** implements a thread-local std::vector<T> with methods: `Push_back(...)`, `operator[]`, `Begin()`, `End()`, `Clear()`, `Size()`, `Pop_back()`
- **G4MapCache<K,V>** implements a thread-local std::map<K,V> with methods: `Insert(...)`, `Begin()`, `End()`, `Find(...)`, `Size()`, `Get(...)`, `Erase(...)`, `operator[]` and introduces the method `Has(...)`

A detailed example of the use of these cache classes is discussed in the unit test `source/global/management/test/testG4Cache.cc`.

### 2.14.3.4.2. G4AutoDelete namespace

During the discussion about G4Cache we have shown the example of storing a pointer to a dynamically created object. A common problem is to correctly delete this object at the end of its lifecycle. Since the G4Class instance is thread-shared, it is not possible to delete the cached object in the destructor of G4Class because it is called by the master and the thread-local instances of the cached object will not be deleted. In some cases, to solve this problem, it is possible to use a helper introduced in the namespace **G4AutoDelete**. A simplified garbage collection mechanism without reference counting is implemented:

```cpp
#include "G4AutoDelete.hh"
void G4Class::bar() {
  //Get a thread-local value:
  G4Something* local = fValue.Get();
  if ( local == 0 ) {
    local = new G4Something( ... );
    G4AutoDelete::Register( local ); //All thread instances will be delete automatically
  }
}
```

This technique will delete all instances of the registered objects **at the end of the program**, after the main function has returned (if they would have been declared `static`).

This method has several limitations:

i. Registered objects will be deleted only at the end of the program
ii. The order in which objects of different type will be deleted is not specified
iii. Once an object is registered it cannot be deleted anymore explicitly by user
iv. The objects that are registered with this method cannot contain data filed marked G4ThreadLocal and cannot be a split-classes
v. Registered object cannot make use of **G4Allocator** functionalities
vi. These restrictions apply to all data members for which the class owns property

In addition, since the objects will be deleted after the main program exit in a non-specified order, it is recommended to provide a very simple destructor that does not depend on other objects (in particular should not call any kernel functionality).

### 2.14.3.4.3. Thread Private singleton

In Geant4 the singleton pattern is used in several cases. The majority of the managers are implemented via the singleton pattern, that in the most simple implementation is:

```cpp
class G4Singleton {
  public:
    G4Singleton* GetInstance() {
      static G4Singleton anInstance;
      return &anInstance;
    }
};
```
With multi-threading many managers and singletons are thread-local. For this reason they have been transformed to:

```cpp
class G4Singleton {
private:
    static G4ThreadLocal* instance;
public:
    G4Singleton* GetInstance() {
        if (instance == 0) instance = new G4Singleton;
        return instance;
    }
};
```

This causes a memory leak: it is not possible to delete thread-local instances of the singletons. To solve this problem the class `G4ThreadLocalSingleton` has been added to the toolkit. This template class has a single public method `T* G4ThreadLocalSingleton<T>::Instance()` that returns a pointer to a thread-local instance of T. The thread-local instances of T will be deleted, similarly to the case of G4Cache, at the end of the program.

The example code can be transformed to:

```cpp
#include "G4ThreadLocalSingleton.hh"
class G4Singleton {
    friend class G4ThreadLocalSingleton>G4Singleton<;
public:
    G4Singleton* GetInstance() {
        static G4ThreadLocalSingleton>G4Singleton< theInstance;
        return theInstance.Instance();
    }
};
```

### 2.14.4. Threading model utilities and functions

Geant4 parallelism is based on POSIX standards and in particular on the `pthreads` library. However all functionalities have been wrapped around Geant4 specific names. This will allow to include WIN32 threading model. In the following a list of the main functionalities available in the `global/management` category are discussed.

#### 2.14.4.1. Types and functions related to the use of threads

`G4Thread` defines the type for threads (POSIX `pthread_t`). The types `G4ThreadFunReturnType` and `G4ThreadFunArgType` define respectively the return value and the argument type for a function executed in a thread. Use `G4THREADCREATE` and `G4THREADJOIN` macros to respectively create and join a thread. `G4Pid_t` is the type for the PID of a thread.

Example:

```cpp
#include "G4Threading.hh"

// Define a thread-function using G4 types
G4ThreadFunReturnType myfunc( G4ThreadFunArgType val) {
    double value = *(double*)val;
    MESSAGE("value is:"<<value);
    return /*(G4ThreadFunReturnType)*/NULL;
}

// Example: spawn 10 threads that execute myfunc
int main(int,char**) {
    MESSAGE("Starting program ");
    int nthreads = 10;
    G4Thread* tid = new G4Thread[nthreads];
    double *valss = new double[nthreads];
    for ( int idx = 0 ; idx < nthreads ; ++idx ) {
        // Spawn a thread
        G4THREADCREATE(tid[idx],<valss+idx>,myfunc);
        // Join the thread
        G4THREADJOIN(tid[idx]);
    }
    delete[] valss;
    delete[] tid;
    return 0;
}
2.14.4.2. Types and functions related to the use of mutexes and conditions

**G4Mutex** is the type for mutexes in Geant4 (POSIX pthread_mutex_t). The **G4MUTEX_INITIALIZER** and **G4MUTEXINIT** macros are used to initialize a mutex. Use **G4MUTEXLOCK** and **G4MUTEXUNLOCK** functions to lock/unlock a mutex. **G4AutoLock** class helps the locking/unlocking of a mutex and should be always be used instead of **G4MUTEXLOCK/UNLOCK**.

Example:

```cpp
#include "G4Threading.hh"
#include "G4AutoLock.hh"

//Create a global mutex
G4Mutex mutex = G4MUTEX_INITIALIZER;
//Alternatively, call in the main function G4MUTEXINIT(mutex);

//A shared resource (i.e. manipulated by all threads)
G4int aValue = 1;

G4ThreadFunReturnType myfunc( G4ThreadFunArgType ) {
    //Explicit lock/unlock
    G4MUTEXLOCK(&mutex);
    ++aValue;
    G4MUTEXUNLOCK(&mutex);
    //The following should be used instead of the previous because it guarantees automatic
    //unlock of mutex.
    //When variable l goes out of scope, G4MUTEXUNLOCK is automatically called
    G4AutoLock l(&mutex);
    --aValue;
    //Explicit lock/unlock. Note that lock/unlock is only tried if mutex is already locked/unlock
    l.lock();
    l.lock();//No problem here
    ++aValue;
    l.unlock();
    l.lock();
    --aValue;
    return /*(G4ThreadFunReturnType)*/NULL;
}
```

A complete example of the usage of these functionalities is discussed in the unit test `source/global/management/test/ThreadingTest.cc`.

Conditions are also available via the **G4Condition** type, the **G4CONDITION_INITIALIZER** macro and the two functions **G4CONDITIONWAIT** and **G4CONDITIONBROADCAST**. The use of condition allows to implement the barrier mechanism (e.g. synchronization point for threads). A detailed example on the use of condition and how to implement correctly a barrier is discussed in **G4MTRunManager** code (at the end of file `source/run/src/G4MTRunManager.cc`). In general there should be no need for kernel classes (with the exception of run category) to use conditions since threads are considered independent and do not need to communicate between them.

### 2.14.5. Additional material

In this chapter we have discussed in detail what are probably the most critical aspects of multi-threading capabilities in Geant4. Additional material can be found in online resources. The main entry point is the Geant4 multi-threading task-force twiki page. The **Application Developers Guide** contains general information regarding multi-threading that is also relevant for Toolkit Developers.
A beginner guide to multi-threading targeted to Geant4 developers has been presented during the 18th Collaboration Meeting: agenda

For additional information consult this page and this page

Several contributions at the 18th Collaboration Meeting discuss multi-threading:

• Plenary Session 3 - Geant4 version 10 (part 1): agenda
• Hadronics issues related to MT: agenda
• Developments for multi-threading: work-spaces: contribution
• Status of the planned developments: coding guidelines, MT migration, g4tools migration, code review: contribution
• G4MT CP on MIC Architecture: contribution

Finally few articles and proceedings have been prepared:

• S. Ahn et al, Geant4-MT: bringing multi-threaded Geant4 into production, to be published in SNA&MC2013 proceeding

[Status of this chapter]

December 2013 - First version. Adapted from Multi-threading task-force twiki web-pages
Chapter 3. Extending Toolkit Functionality

3.1. Geometry

3.1.1. What can be extended?

Geant4 already allows a user to describe any desired solid, and to use it in a detector description, in some cases, however, the user may want or need to extend Geant4’s geometry. One reason can be that some methods and types in the geometry are general and the user can utilise specialised knowledge about his or her geometry to gain a speedup. The most evident case where this can happen is when a particular type of solid is a key element for a specific detector geometry and an investment in improving its runtime performance may be worthwhile.

To extend the functionality of the Geometry in this way, a toolkit developer must write a small number of methods for the new solid. We will document below these methods and their specifications. Note that the implementation details for some methods are not a trivial matter: these methods must provide the functionality of finding whether a point is inside a solid, finding the intersection of a line with it, and finding the distance to the solid along any direction. However once the solid class has been created with all its specifications fulfilled, it can be used like any Geant4 solid, as it implements the abstract interface of G4VSolid.

Other additions can also potentially be achieved. For example, an advanced user could add a new way of creating physical volumes. However, because each type of volume has a corresponding navigator helper, this would require to create a new Navigator as well. To do this the user would have to inherit from G4Navigator and modify the new Navigator to handle this type of volumes. This can certainly be done, but will probably be made easier to achieve in the future versions of the Geant4 toolkit.

3.1.2. Adding a new type of Solid

We list below the required methods for integrating a new type of solid in Geant4. Note that Geant4’s specifications for a solid pay significant attention to what happens at points that are within a small distance (tolerance, kCarTolerance in the code) of the surface. So special care must be taken to handle these cases in considering all different possible scenarios, in order to respect the specifications and allow the solid to be used correctly by the other components of the geometry module.

Creating a derived class of G4VSolid

The solid must inherit from G4VSolid or one of its derived classes and implement its virtual functions.

Mandatory member functions you must define are the following pure virtual of G4VSolid:

EInside Inside(const G4ThreeVector& p)
G4double DistanceToIn(const G4ThreeVector& p)
G4double DistanceToIn(const G4ThreeVector& p, const G4ThreeVector& v)
G4ThreeVector SurfaceNormal(const G4ThreeVector& p)
G4double DistanceToOut(const G4ThreeVector& p)
G4double DistanceToOut(const G4ThreeVector& p, const G4ThreeVector& v,
    const G4bool calcNorm=false,
    G4bool *validNorm=0, G4ThreeVector *n)
G4bool CalculateExtent(const EAxis pAxis,
    const G4VoxelLimits& pVoxelLimit,
    const G4AffineTransform& pTransform,
    G4double& pMin,
    G4double& pMax) const
G4GeometryType GetEntityType() const
std::ostream& StreamInfo(std::ostream& os) const

They must perform the following functions

EInside Inside(const G4ThreeVector& p)

This method must return:
Extending Toolkit Functionality

- **kOutside** if the point at offset \( p \) is outside the shape boundaries plus \( \text{Tolerance}/2 \),
- **kSurface** if the point is \( \leq \text{Tolerance}/2 \) from a surface, or
- **kInside** otherwise.

```cpp
G4ThreeVector SurfaceNormal(const G4ThreeVector& p)
```

Return the outwards pointing unit normal of the shape for the surface closest to the point at offset \( p \).

```cpp
G4double DistanceToIn(const G4ThreeVector& p)
```

Calculate distance to nearest surface of shape from an outside point \( p \). The distance can be an underestimate.

```cpp
G4double DistanceToIn(const G4ThreeVector& p, const G4ThreeVector& v)
```

Return the distance along the normalised vector \( v \) to the shape, from the point at offset \( p \). If there is no intersection, return \( \text{kJInfinity} \). The first intersection resulting from `leaving` a surface/volume is discarded. Hence, this is tolerant of points on surface of shape.

```cpp
G4double DistanceToOut(const G4ThreeVector& p)
```

Calculate distance to nearest surface of shape from an inside point. The distance can be an underestimate.

```cpp
G4double DistanceToOut(const G4ThreeVector& p, const G4ThreeVector& v, const G4bool calcNorm=false, G4bool *validNorm=0, G4ThreeVector *n=0);
```

Return distance along the normalised vector \( v \) to the shape, from a point at an offset \( p \) inside or on the surface of the shape. Intersections with surfaces, when the point is not greater than \( \text{kCarTolerance}/2 \) from a surface, must be ignored.

If `calcNorm` is true, then it must also set `validNorm` to either
- **true**, if the solid lies entirely behind or on the exiting surface. Then it must set \( n \) to the outwards normal vector (the Magnitude of the vector is not defined).
- **false**, if the solid does not lie entirely behind or on the exiting surface.

If `calcNorm` is false, then `validNorm` and \( n \) are unused.

```cpp
```

Calculate the minimum and maximum extent of the solid, when under the specified transform, and within the specified limits. If the solid is not intersected by the region, return false, else return true.

```cpp
G4GeometryType GetEntityType() const;
```

Provide identification of the class of an object (required for persistency and STEP interface).

```cpp
std::ostream& StreamInfo(std::ostream& os) const
```

Should dump the contents of the solid to an output stream.

The method:
Extending Toolkit Functionality

G4double GetCubicVolume()

should be implemented for every solid in order to cache the computed value (and therefore reuse it for future calls to the method) and to eventually implement a precise computation of the solid's volume. If the method will not be overloaded, the default implementation from the base class will be used (estimation through a Monte Carlo algorithm) and the computed value will not be stored.

There are a few member functions to be defined for the purpose of visualisation. The first method is mandatory, and the next four are not.

```
// Mandatory
virtual void DescribeYourselfTo (G4VGraphicsScene& scene) const = 0;

// Not mandatory
virtual G4VisExtent GetExtent() const;
virtual G4Polyhedron* CreatePolyhedron () const;
virtual G4NURBS* CreateNURBS () const;
virtual G4Polyhedron* GetPolyhedron () const;
```

What these methods should do and how they should be implemented is described here.

```
void DescribeYourselfTo (G4VGraphicsScene& scene) const;
```

This method is required in order to identify the solid to the graphics scene. It is used for the purposes of "double dispatch". All implementations should be similar to the one for G4Box:

```
void G4Box::DescribeYourselfTo (G4VGraphicsScene& scene) const
{
    scene.AddSolid (*this);
}
```

The method:

```
G4VisExtent GetExtent() const;
```

provides extent (bounding box) as a possible hint to the graphics view. You must create it by finding a box that encloses your solid, and returning a VisExtent that is created from this. The G4VisExtent must presumably be given the minus x, plus x, minus y, plus y, minus z and plus z extents of this "box". For example a cylinder can say

```
G4VisExtent G4Tubs::GetExtent() const
{
    // Define the sides of the box into which the G4Tubs instance would fit.
    return G4VisExtent (-fRMax, fRMax, -fRMax, fRMax, -fDz, fDz);
}
```

The method:

```
G4Polyhedron* CreatePolyhedron () const;
```

is required by the visualisation system, in order to create a realistic rendering of your solid. To create a G4Polyhedron for your solid, consult G4Polyhedron.

While the method:

```
G4Polyhedron* GetPolyhedron () const;
```

is a "smart" access function that creates on requests a polyhedron and stores it for future access and should be customised for every solid.

The method:
is not currently utilised, so you do not have to implement it.

### 3.1.3. Modifying the Navigator

For the vast majority of use-cases, it is not indeed necessary (and definitely not advised) to extend or modify the existing classes for navigation in the geometry. A possible use-case for which this may apply, is for the description of a new kind of physical volume to be integrated. We believe that our set of choices for creating physical volumes is varied enough for nearly all needs. Future extensions of the Geant4 toolkit will probably make easier exchanging or extending the G4Navigator, by introducing an abstraction level simplifying the customisation. At this time, a simple abstraction level of the navigator is provided by allowing overloading of the relevant functionalities.

**Extending the Navigator**

The main responsibilities of the Navigator are:

- locate a point in the tree of the geometrical volumes;
- compute the length a particle can travel from a point in a certain direction before encountering a volume boundary.

The Navigator utilises one helper class for each type of physical volume that exists. You will have to reuse the helper classes provided in the base Navigator or create new ones for the new type of physical volume.

To extend G4Navigator you will have then to inherit from it and modify these functions in your ModifiedNavigator to request the answers for your new physical volume type from the new helper class. The ModifiedNavigator should delegate other cases to the Geant4's standard Navigator.

**Replacing the Navigator**

Replacing the Navigator is another possible operation. It is similar to extending the Navigator, in that any types of physical volume that will be allowed must be handled by it. The same functionality is required as described in the previous section.

However the amount of work is probably potentially larger, if support for all the current types of physical volumes is required.

The Navigator utilises one helper class for each type of physical volume that exists. These could also potentially be replaced, allowing a simpler way to create a new navigation system.

### 3.2. Electromagnetic Fields

#### 3.2.1. Creating a New Type of Field

Geant4 currently handles magnetic and electric fields and, in future releases, will handle combined electromagnetic fields. Fields due to other forces, not yet included in Geant4, can be provided by describing the new field and the force it exerts on a particle passing through it. For the time being, all fields must be time-independent. This restriction may be lifted in the future.

In order to accommodate a new type of field, two classes must be created: a field type and a class that determines the force. The Geant4 system must then be informed of the new field.

**A new Field class**

A new type of Field class may be created by inheriting from G4Field
void GetFieldValue( const double Point[3],
    double *pField )=0;
}

and deciding how many components your field will have, and what each component represents. For example, three
components are required to describe a vector field while only one component is required to describe a scalar field.

If you want your field to be a combination of different fields, you must choose your convention for which field goes
first, which second etc. For example, to define an electromagnetic field we follow the convention that components
0, 1 and 2 refer to the magnetic field and components 3, 4 and 5 refer to the electric field.

By leaving the GetFieldValue method pure virtual, you force those users who want to describe their field to create
a class that implements it for their detector's instance of this field. So documenting what each component means
is required, to give them the necessary information.

For example someone can describe DetectorAbc's field by creating a class DetectorAbcField, that derives from
your NewField

```cpp
class DetectorAbcField : public NewField
{
    public:
        void MyFieldGradient::GetFieldValue( const double Point[3],
            double *pField );
};
```

They then implement the function GetFieldValue

```cpp
void MyFieldGradient::GetFieldValue( const double Point[3],
            double *pField )
{
    // We expect pField to point to pField[9];
    // This & the order of the components of pField is your own
    // convention
    // We calculate the value of pField at Point ...
}
```

A new Equation of Motion for the new Field

Once you have created a new type of field, you must create an Equation of Motion for this Field. This is required
in order to obtain the force that a particle feels.

To do this you must inherit from G4Mag_EqRhs and create your own equation of motion that understands your
field. In it you must implement the virtual function EvaluateRhsGivenB. Given the value of the field, this function
calculates the value of the generalised force. This is the only function that a subclass must define.

```cpp
virtual void EvaluateRhsGivenB( const G4double y[],
    const G4double B[3],
    G4double dydx[] ) const = 0;
```

In particular, the derivative vector \( \mathbf{dydx} \) is a vector with six components. The first three are the derivative of
the position with respect to the curve length. Thus they should set equal to the normalised velocity, which is
components 3, 4 and 5 of \( y \).

\[
(dydx[0], dydx[1], dydx[2]) = (y[3], y[4], y[5])
\]

The next three components are the derivatives of the velocity vector with respect to the path length. So you should
write the "force" components for

\[
dydx[3], dydx[4] \text{ and } dydx[5]
\]

for your field.
**Get a G4FieldManager to use your field**

In order to inform the Geant4 system that you want it to use your field as the global field, you must do the following steps:

1. Create a Stepper of your choice:

   ```
yourStepper = new G4ClassicalRK( yourEquationOfMotion );
   // or if your field is not smooth eg
   //     new G4ImplicitEuler( yourEquationOfMotion );
   ```

2. Create a chord finder that uses your Field and Stepper. You must also give it a minimum step size, below which it does not make sense to attempt to integrate:

   ```
yourChordFinder= new G4ChordFinder( yourField,
   yourMininumStep, // say 0.01*mm
   yourStepper );
   ```

3. Next create a G4FieldManager and give it that chord finder,

   ```
yourFieldManager= new G4FieldManager();
   yourFieldManager.SetChordFinder(yourChordFinder);
   ```

4. Finally we tell the Geometry that this FieldManager is responsible for creating a field for the detector.

   ```
G4TransportationManager::GetTransportationManager()
   -> SetFieldManager( yourFieldManager );
   ```

**Changes for non-electromagnetic fields**

If the field you are interested in simulating is not electromagnetic, another minor modification may be required. The transportation currently chooses whether to propagate a particle in a field or rectilinearly based on whether the particle is charged or not. If your field affects non-charged particles, you must inherit from the G4Transportation and re-implement the part of GetAlongStepPhysicalInteractionLength that decides whether the particles is affected by your force.

In particular the relevant section of code does the following:

```
// Does the particle have an (EM) field force exerting upon it?
//
// if( (particleCharge!=0.0) ){  
  fieldExertsForce= this->DoesGlobalFieldExist();
  // Future: will/can also check whether current volume's field is Zero or
  // set by the user (in the logical volume) to be zero.
}
```

and you want it to ask whether it feels your force. If, for the sake of an example, you wanted to see the effects of gravity on a heavy hypothetical particle, you could say

```
// Does the particle have my field's force exerted on it?
//
if (particle->GetName() == "VeryHeavyWIMP") {
  fieldExertsForce= this->DoesGlobalFieldExist(); // For gravity
}
```

After doing all these steps, you will be able to see the effects of your force on a particle’s motion.

3.3. Particles

3.3.1. Properties of particles

The G4ParticleDefinition class has properties to characterize individual particles, such as name, mass, charge, spin, and so on. Properties of particles are set during initialization of each particle. Default values of particle properties are described in each particles class. In addition, properties of heavy nuclei can be given by external files. Basically, these properties can not be changed after initialization phase except for ones related its decay; life time, branching ratio of each decay mode and the "stable" flag. However, Geant4 provides a method to override these properties by using external files.

Properties of nuclei

Individual classes are provided for light nuclei (i.e. deuteron, triton, He3, and He4) with default values of their properties. Other nuclei are dynamically created by requests from processes (and users). G4IonTable class handles creation of such ions. Default properties of nuclei are determined with help of G4NuclearProperties.

Users can register a G4IsotopeTable to the G4IonTable. G4IsotopeTable describes properties of ions which are used to create ions. You can get exited energy, decay modes, and life time for relatively long life nuclei by using G4RIsotopeTable and data files (G4RADIOACTIVEDATA should be set to the directory where data files exist). G4IsotopeMagneticMomentTable provides a table of magnetic moment of nuclei with the data file of G4IsotopeMagneticMoment.table (The file name should be set to G4IONMAGNETICMOMENT). 

Changing particle properties

Only in "PreInit" phase, properties can be modified with help of G4ParticlePropertyTable class. Particle properties can be overridden with the method

```cpp
G4bool SetParticleProperty(const G4ParticlePropertyData& newProperty)
```

by setting new values in G4ParticlePropertyData. In addition, the current values of particles properties can be extracted into text files by using G4TextPPReporter. On the other hand, G4TextPPRetriever can change particle properties according to text files.

3.3.2. Adding New Particles

You can add a new particle by creating a new class for it. The new class should be derived from G4ParticleDefinition. You can find an example under examples/extended/exoticphysics/monopole. A new class for the monopole is defined as follows;

```cpp
class G4Monopole : public G4ParticleDefinition
{
private:
  static G4Monopole* theMonopole;
  G4Monopole()
  { 
    const G4String& aName, G4double mass, 
    G4double width, G4double charge, 
    G4int iSpin, G4int iParity, 
    G4int iConjugation, G4int iIsospin, 
    G4int iIsospin3, G4int gParity, 
    G4int iType, G4int lepton, 
    G4int baryon, G4int encoding, 
    G4bool stable, G4double lifetime, 
    G4DecayTable * decayTable );
  
public:
  virtual ~G4Monopole();
  static G4Monopole* MonopoleDefinition();
};
```
Extending Toolkit Functionality

```cpp
static G4Monopole* Monopole();
```

Static methods above need to be defined and implemented so that this new particle instance will be created in ConstructParticles method of your physics list. You can add new properties if necessary (G4Monopole has a property for magnetic charge) Values of properties need to be given in the static method as other particle classes.

```cpp
G4Monopole* G4Monopole::MonopoleDefinition(G4double mass, G4int mCharge, G4int eCharge)
{
    if(!theMonopole) {
        theMonopole = new G4Monopole(
            "monopole",         mass,       0.0*MeV,           0,
            0,               0,             0,
            0,               0,             0,
            "boson",               0,             0,           0,
            true,            -1.0,             0);
    }
    return theMonopole;
}
```

### 3.3.3. Nuclide properties from Evaluated Nuclear Structure Data File

**G4NuclideTable**

*G4NuclideTable* have been introduced at Geant4 v10 to provide properties of nuclide states. Excitation energy and decay constant of each state are listed in the table. Spin and dipole magnetic moment are given for some states. Source of data of the table is ENSDF of August 2012. 24,359 states are extracted from the source. Ground states and excite states having longer half-life than 1 nano second are implemented in source code of the class. Total number of the hard coded states is 6807 and they are sufficient for most use cases, thus the *G4NuclideTable* works within them by default. Full set of 24,359 states is embodied in a data file. *G4NuclideTable* will use the data file by getting an environment variable of "G4ENSDFSTATEDATA". To get very fine position and time record about level transitions of nuclides, user may want to transport very short lived excite states in his simulation. The environment variable must be set by user in calculating such simulation. To improve performance, ground states and long lived excite states are prepared in initialization and loaded into kernel. *G4NuclideTable* controls the threshold of half-life of these preload states. Default value of the threshold is 1 micro second and user can modify the value. If user wants to change the value shorter than 1 nano second, then he must set the environment variable before.

**Isomer levels**

*G4NuclideTable* provides an integer that represents isomer level of each state. Because of limitation of PDG codes, only a number from 0 to 9 is allowed as the value of level. All ground states have 0 as the value. The lowest energy state isomers in preloaded states have the isomer level of 1. Two will be given for the second lowest isomers among preloaded states and this procedure continues until 8. After this all excite states will have 9 as its isomer level. This numbering scheme of isomer levels only happens within preload states and value of isomer level for certain excite state depends on threshold of half-life for preload states. All excite states dynamically generated within event loop will have 9 as its isomer level.

**Adding states**

User is able to add states into the table with user specific value of excitation energy, decay constant, spin and dipole magnetic moment. This should be done in initialization phase then user-defined states will be in preload states. However they always have isomer level of 9 and be neglected in numbering of isomer level of other states.

Currently *G4RadioactiveDecay* and *G4PhotoEvaporation* models share the state information with *G4NuclideTable*. Other models are encouraged to follow these.

3.5. Hadronic Physics

3.5.1. Introduction

Optimal exploitation of hadronic final states played a key role in successes of all recent collider experiment in HEP, and the ability to use hadronic final states will continue to be one of the decisive issues during the analysis phase of the LHC experiments. Monte Carlo programs like Geant4 facilitate the use of hadronic final states, and have been developed for many years.

We give an overview of the Object Oriented frameworks for hadronic generators in Geant4, and illustrate the physics models underlying hadronic shower simulation on examples, including the three basic types of modeling: data-driven, parametrisation-driven, and theory-driven modeling, and their possible realisations in the Object Oriented component system of Geant4. We put particular focus on the level of extendibility that can and has been achieved by our Russian dolls approach to Object Oriented design, and the role and importance of the frameworks in a component system.

3.5.2. Principal Considerations

The purpose of this section is to explain the implementation frameworks used in and provided by Geant4 for hadronic shower simulation as in the 1.1 release of the program. The implementation frameworks follow the Russian dolls approach to implementation framework design. A top-level, very abstracting implementation framework provides the basic interface to the other Geant4 categories, and fulfills the most general use-case for hadronic shower simulation. It is refined for more specific use-cases by implementing a hierarchy of implementation frameworks, each level implementing the common logic of a particular use-case package in a concrete implementation of the interface specification of one framework level above, this way refining the granularity of abstraction and delegation. This defines the Russian dolls architectural pattern. Abstract classes are used as the delegation mechanism.

All framework functional requirements were obtained through use-case analysis. In the following we present for each framework level the compressed use-cases, requirements, designs including the flexibility provided, and illustrate the framework functionality with examples. All design patterns cited are to be read as defined in [ Gamma1995 ].

3.5.3. Level 1 Framework - processes

There are two principal use-cases of the level 1 framework. A user will want to choose the processes used for his particular simulation run, and a physicist will want to write code for processes of his own and use these together with the rest of the system in a seamless manner.

Requirements

1. Provide a standard interface to be used by process implementations.
2. Provide registration mechanisms for processes.

\footnote{The same can be achieved with template specialisations with slightly improved CPU performance but at the cost of significantly more complex designs and, with present compilers, significantly reduced portability.}
Design and interfaces

Both requirements are implemented in a sub-set of the tracking-physics interface in Geant4. The class diagram is shown in Figure 3.1.

Figure 3.1. Level 1 implementation framework of the hadronic category of GEANT4.

All processes have a common base-class G4VProcess, from which a set of specialised classes are derived. Three of them are used as base classes for hadronic processes for particles at rest (G4VRestProcess), for interactions in flight (G4VDiscreteProcess), and for processes like radioactive decay where the same implementation can represent both these extreme cases (G4VRestDiscreteProcess).

Each of these classes declares two types of methods; one for calculating the time to interaction or the physical interaction length, allowing tracking to request the information necessary to decide on the process responsible for final state production, and one to compute the final state. These are pure virtual methods, and have to be implemented in each individual derived class, as enforced by the compiler.

Framework functionality

The functionality provided is through the use of process base-class pointers in the tracking-physics interface, and the G4Process-Manager. All functionality is implemented in abstract, and registration of derived process classes with the G4Process-Manager of an individual particle allows for arbitrary combination of both Geant4 provided processes, and user-implemented processes. This registration mechanism is a modification on a Chain of Responsibility. It is outside the scope of the current paper, and its description is available from G4Manual.

3.5.4. Level 2 Framework - Cross Sections and Models

At the next level of abstraction, only processes that occur for particles in flight are considered. For these, it is easily observed that the sources of cross sections and final state production are rarely the same. Also, different sources will come with different restrictions. The principal use-cases of the framework are addressing these commonalities. A user might want to combine different cross sections and final state or isotope production models as provided by Geant4, and a physicist might want to implement his own model for particular situation, and add cross-section data sets that are relevant for his particular analysis to the system in a seamless manner.

Requirements

1. Flexible choice of inclusive scattering cross-sections.
2. Ability to use different data-sets for different parts of the simulation, depending on the conditions at the point of interaction.
3. Ability to add user-defined data-sets in a seamless manner.
4. Flexible, unconstrained choice of final state production models.
5. Ability to use different final state production codes for different parts of the simulation, depending on the conditions at the point of interaction.
6. Ability to add user-defined final state production models in a seamless manner.
7. Flexible choice of isotope production models, to run in parasitic mode to any kind of transport models.
8. Ability to use different isotope production codes for different parts of the simulation, depending on the conditions at the point of interaction.
9. Ability to add user-defined isotope production models in a seamless manner.

**Design and interfaces**

The above requirements are implemented in three framework components, one for cross-sections, final state production, and isotope production each. The class diagrams are shown in Figure 3.2 for the cross-section aspects, Figure 3.3 for the final state production aspects, and figure Figure 3.4 for the isotope production aspects.

![Figure 3.2. Level 2 implementation framework of the hadronic category of Geant4; cross-section aspect.](image)

![Figure 3.3. Level 2 implementation framework of the hadronic category of Geant4; final state production aspect.](image)
Extending Toolkit Functionality

Figure 3.4. Level 2 implementation framework of the hadronic category of Geant4; isotope production aspect

The three parts are integrated in the G4Hadronic-Process class, that serves as base-class for all hadronic processes of particles in flight.

Cross-sections

Each hadronic process is derived from G4Hadronic-Process), which holds a list of "cross section data sets". The term "data set" is representing an object that encapsulates methods and data for calculating total cross sections for a given process in a certain range of validity. The implementations may take any form. It can be a simple equation as well as sophisticated parameterisations, or evaluated data. All cross section data set classes are derived from the abstract class G4VCrossSection-DataSet), which declares methods that allow the process inquire, about the applicability of an individual data-set through IsApplicable(const G4DynamicParticle*, const G4Element*), and to delegate the calculation of the actual cross-section value through GetCrossSection(const G4DynamicParticle*, const G4Element*).

Final state production

The G4HadronicInteraction base class is provided for final state generation. It declares a minimal interface of only one pure virtual method: G4VParticleChange* ApplyYourself(const G4Track &, G4Nucleus &). G4HadronicProcess provides a registry for final state production models inheriting from G4Hadronic-Interaction. Again, final state production model is meant in very general terms. This can be an implementation of a quark gluon string model [QGSM], a sampling code for ENDF/B data formats [ENDFForm], or a parametrisation describing only neutron elastic scattering off Silicon up to 300–MeV.

Isotope production

For isotope production, a base class (G4VIsotope-Production) is provided. It declares a method G4IsoResult * GetIsotope(const G4Track &, const G4Nucleus &) that calculates and returns the isotope production information. Any concrete isotope production model will inherit from this class, and implement the method. Again, the modeling possibilities are not limited, and the implementation of concrete production models is not restricted in any way. By convention, the GetIsotope method returns NULL, if the model is not applicable for the current projectile target combination.

Framework functionality:

Cross Sections

G4HadronicProcess provides registering possibilities for data sets. A default is provided covering all possible conditions to some approximation. The process stores and retrieves the data sets through a data store that acts like a FILO stack (a Chain of Responsibility with a First In Last Out decision strategy). This allows the user to map out
Extending Toolkit Functionality

the entire parameter space by overlaying cross section data sets to optimise the overall result. Examples are the cross sections for low energy neutron transport. If these are registered last by the user, they will be used whenever low energy neutrons are encountered. In all other conditions the system falls back on the default, or data sets with earlier registration dates. The fact that the registration is done through abstract base classes with no side-effects allows the user to implement and use his own cross sections. Examples are special reaction cross sections of $\Xi^0$-nuclear interactions that might be used for $#/#'$ analysis at LHC to control the systematic error.

Final state production

The G4HadronicProcess class provides a registration service for classes deriving from G4Hadronic-Interaction, and delegates final state production to the applicable model. G4Hadronic-Interaction provides the functionality needed to define and enforce the applicability of a particular model. Models inheriting from G4Hadronic-Interaction can be restricted in applicability in projectile type and energy, and can be activated/deactivated for individual materials and elements. This allows a user to use final state production models in arbitrary combinations, and to write his own models for final state production. The design is a variant of a Chain of Responsibility. An example would be the likely CMS scenario - the combination of low energy neutron transport with a quantum molecular dynamics [QMD], invariant phase space decay [CHIPS], and fast parametrised models for calorimeter materials, with user defined modeling of interactions of spallation nucleons with the most abundant tracker and calorimeter materials.

Isotope production

The G4HadronicProcess by default calculates the isotope production information from the final state given by the transport model. In addition, it provides a registering mechanism for isotope production models that run in parasite mode to the transport models and inherit from G4VIsootope-Production. The registering mechanism behaves like a FILO stack, again based on Chain of Responsibility. The models will be asked for isotope production information in inverse order of registration. The first model that returns a non-NULL value will be applied. In addition, the G4HadronicProcess provides the basic infrastructure for accessing and steering of isotope-production information. It allows to enable and disable the calculation of isotope production information globally, or for individual processes, and to retrieve the isotope production information through the G4IsoParticleChange * GetIsotopeProductionInfo() method at the end of each step. The G4HadronicProcess is a finite state machine that will ensure the GetIsotope-ProductionInfo returns a non-zero value only at the first call after isotope production occurred. An example of the use of this functionality is the study of activation of a Germanium detector in a high precision, low background experiment.

3.5.5. Level 3 Framework - Theoretical Models

Geant4 provides at present one implementation framework for theory driven models. The main use-case is that of a user wishing to use theoretical models in general, and to use various intra-nuclear transport or pre-compound models together with models simulating the initial interactions at very high energies.

Requirements

1. Allow to use or adapt any string-parton or parton transport [VNI],
2. Allow to adapt event generators, ex. [PYTHIA7], state production in shower simulation.
3. Allow for combination of the above with any intra-nuclear transport (INT).
5. Allow for combination of the above with any pre-compound model.
6. Allow stand-alone use of any pre-compound model.
7. Allow for use of any evaporation code.
8. Allow for seamless integration of user defined components for any of the above.

**Design and interfaces**

To provide the above flexibility, the following abstract base classes have been implemented:

- G4VHighEnergyGenerator
- G4VIntranuclearTransportModel
- G4VPreCompoundModel
- G4VExcitationHandler

In addition, the class G4TheoFS-Generator is provided to orchestrate interactions between these classes. The class diagram is shown in Figure 3.5.

G4VHighEnergy-Generator serves as base class for parton transport or parton string models, and for Adapters to event generators. This class declares two methods, Scatter, and GetWoundedNucleus.

The base class for INT inherits from G4Hadronic-Interaction, making any concrete implementation usable as a stand-alone model. In doing so, it re-declares the ApplyYourself interface of G4Hadronic-Interaction, and adds a second interface, Propagate, for further propagation after high energy interactions. Propagate takes as arguments a three-dimensional model of a wounded nucleus, and a set of secondaries with energies and positions.

The base class for pre-equilibrium decay models, G4VPre-CompoundModel, inherits from G4Hadronic-Interaction, again making any concrete implementation usable as stand-alone model. It adds a pure virtual DeExcite method for further evolution of the system when intra-nuclear transport assumptions break down. DeExcite takes a G4Fragment, the Geant4 representation of an excited nucleus, as argument.

The base class for evaporation phases, G4VExcitation-Handler, declares an abstract method, BreakItUP(), for compound decay.

**Framework functionality**

The G4TheoFSGenerator class inherits from G4Hadronic-Interaction, and hence can be registered as a model for final state production with a hadronic process. It allows a concrete implementation of G4VIntranuclear-TransportModel and G4VHighEnergy-Generator to be registered, and delegates initial interactions, and intra-nuclear transport of the corresponding secondaries to the respective classes.

The design is a complex variant of a Strategy. The most spectacular application of this pattern is the use of parton-string models for string excitation, quark molecular dynamics for correlated string decay, and quantum molecular dynamics for transport, a combination which promises to result in a coherent description of quark gluon plasma in high energy nucleus-nucleus interactions.

The class G4VIntranuclearTransportModel provides registering mechanisms for concrete implementations of G4VPreCompound-Model, and provides concrete intra-nuclear transports with the possibility of delegating pre-compound decay to these models.

G4VPreCompoundModel provides a registering mechanism for compound decay through the G4VExcitation-Handler interface, and provides concrete implementations with the possibility of delegating the decay of a compound nucleus.

The concrete scenario of G4TheoFS-Generator using a dual parton model and a classical cascade, which in turn uses an exciton pre-compound model that delegates to an evaporation phase, would be the following: G4TheoFS-Generator receives the conditions of the interaction; a primary particle and a nucleus. It asks the
dual parton model to perform the initial scatterings, and return the final state, along with the by then damaged nucleus. The nucleus records all information on the damage sustained. G4TheoFS-Generator forwards all information to the classical cascade, that propagates the particles in the already damaged nucleus, keeping track of interactions, further damage to the nucleus, etc.. Once the cascade assumptions break down, the cascade will collect the information of the current state of the hadronic system, like excitation energy and number of excited particles, and interpret it as a pre-compound system. It delegates the decay of this to the exciton model. The exciton model will take the information provided, and calculate transitions and emissions, until the number of excitons in the system equals the mean number of excitons expected in equilibrium for the current excitation energy. Then it hands over to the evaporation phase. The evaporation phase decays the residual nucleus, and the Chain of Command rolls back to G4TheoFS-Generator, accumulating the information produced in the various levels of delegation.

3.5.6. Level 4 Frameworks - String Parton Models and Intra-Nuclear Cascade

The use-cases of this level are related to commonalities and detailed choices in string-parton models and cascade models. They are use-cases of an expert user wishing to alter details of a model, or a theoretical physicist, wishing to study details of a particular model.

Requirements

1. Allow to select string decay algorithm
2. Allow to select string excitation.
3. Allow the selection of concrete implementations of three-dimensional models of the nucleus
4. Allow the selection of concrete implementations of final state and cross sections in intra-nuclear scattering.
Design and interfaces

To fulfil the requirements on string models, two abstract classes are provided, the G4VParton-StringModel and the G4VString-Fragmentation. The base class for parton string models, G4VParton-StringModel, declares the GetStrings() pure virtual method. G4VString-Fragmentation, the pure abstract base class for string fragmentation, declares the interface for string fragmentation.

To fulfill the requirements on intra-nuclear transport, two abstract classes are provided, G4V3DNucleus, and G4VScatterer. At this point in time, the usage of these intra-nuclear transport related classes by concrete codes is not enforced by designs, as the details of the cascade loop are still model dependent, and more experience has to be gathered to achieve standardisation. It is within the responsibility of the implementers of concrete intra-nuclear transport codes to use the abstract interfaces as defined in these classes.

The class diagram is shown in Figure 3.6 for the string parton model aspects, and in Figure 3.7 for the intra-nuclear transport.

Framework functionality

Again variants of Strategy, Bridge and Chain of Responsibility are used. G4VParton-StringModel implements the initialisation of a three-dimensional model of a nucleus, and the logic of scattering. It delegates secondary production to string fragmentation through a G4VString-Fragmentation pointer. It provides a registering service for the concrete string fragmentation, and delegates the string excitation to derived classes. Selection of string excitation is through selection of derived class. Selection of string fragmentation is through registration.

3.5.7. Level 5 Framework - String De-excitation

The use-case of this level is that of a user or theoretical physicist wishing to understand the systematic effects involved in combining various fragmentation functions with individual types of string fragmentation. Note that this framework level is meeting the current state of the art, making extensions and changes of interfaces in subsequent releases likely.

Requirements

1. Allow the selection of fragmentation function.

Design and interfaces

A base class for fragmentation functions, G4VFragmentation-Function, is provided. It declares the GetLightConeZ() interface.
Framework functionality

The design is a basic Strategy. The class diagram is shown in Figure 3.8. At this point in time, the usage of the G4VFragmentation-Function is not enforced by design, but made available from the G4VString-Fragmentation to an implementer of a concrete string decay. G4VString-Fragmentation provides a registering mechanism for the concrete fragmentation function. It delegates the calculation of \( z_f \) of the hadron to split of the string to the concrete implementation. Standardisation in this area is expected.

3.6. Visualisation

This Chapter is intended to be read after Chapter Section 2.12 on Visualisation object oriented design in Part II. Many of the concepts used here are defined there, and it strongly recommended that a writer of a new visualisation driver or trajectory drawer reads Chapter Section 2.12 first. The class structure described there is summarised in Figure 3.9.

![Figure 3.9. Geant Visualisation System Class Diagram](image)

3.6.1. Creating a new graphics driver

To create a new graphics driver for Geant4, it is necessary to implement a new set of three classes derived from the three base classes, G4VGraphicsSystem, G4VSceneHandler and G4VViewer.

3.6.1.1. A useful place to start

A skeleton set of classes is included in the code distribution in the visualisation category under subdirectory visualisation/XXX (but they are not default-registered graphics systems).

There are several sets of classes, described in more detail below. A recommended approach is to copy the files that best match your graphics system to a new subdirectory with a name that suits your graphics system.

Then

1. Change the name of the files (change the code -- XXX or XXXFile, etc., as chosen -- to something that suits your graphics system).
2. Change XXX similarly in all files.
3. Change XXX similarly in name := G4XXX in GNUmakefile.
4. Add your new subdirectory to SUBDIRS and SUBLIBS in visualisation/GNUmakefile.
5. Look at the code and use it to build your visualisation driver. You might also find it useful to look at ASCIIITree (and VTREE) as an example of a minimal graphics driver. Look at FukuiRenderer as an example of a driver which implements AddSolid methods for some solids. Look at OpenGL as an example of a driver which implements a graphical database (display lists) and the machinery to decide when to rebuild. (OpenGL is complicated by the proliferation of combinations of the use or not of display lists for three window systems, X-windows, X with motif (interactive), Microsoft Windows (Win32), a total of six combinations, and much use is made of inheritance to avoid code duplication.)
6. If it requires external libraries, introduce two new environment variables G4VIS_BUILD_XXX_DRIVER and G4VIS_USE_XXX (where XXX is your choice as above) and make the modifications to:

---

2 To do this, simply instantiate and register, for example: visManager->RegisterGraphicsSystem(new G4XXX) before visManager->initialise();
3.6.1.1. Graphics driver templates in the xxx sub-category

You may use the following templates to help you get started writing a graphics driver. (The word “template” is used in the ordinary sense of the word; they are not C++ templates.)

- G4XXX, G4XXXSceneHandler, G4XXXViewer Templates for the simplest possible graphics driver. These would be suitable for an “immediate” driver, i.e., one which renders each object immediately to a screen. Of course, if the view needs re-drawing, as, for example, after a change of viewpoint, the viewer requests a re-issue of drawn objects.
- G4XXXFile, G4XXXFileSceneHandler, G4XXXFileViewer Templates for a file-writing graphics driver. The particular features are: delayed opening of the file on receipt of the first item; rewinding file on ClearView (to simulate the clearing of views and prevent the duplication of material in the file); closing of the file on ShowView, which may also trigger the launch of a browser. There are various degrees of sophistication in, for example, the allocation of filenames -- see FukuiRenderer or HepRepFile.

These templates also show the use of a specific AddSolid function whereby the specific parameters, for example, the dimensions of a G4Box, can be accessed.

- G4XXXStored, G4XXXStoredSceneHandler, G4XXXStoredViewer Templates for a graphics driver with a store/database. The advantage of a store is that the view can be refreshed, for example, from a different viewpoint, without a need to recompute. It is up to the viewer to decide when a re-computation is necessary. They also show how to distinguish between permanent and transient objects -- see also Section Section 3.6.1.6.

- G4XXXSG, G4XXXSGSceneHandler, G4XXXSGViewer Templates for a sophisticated graphics driver with a scene graph. The scene graph, following Open Inventor parlance, is a tree of objects that dictates the order in which the objects are rendered. It obviously lends itself to the rendering of the Geant4 geometry hierarchy. For example, the Open Inventor driver draws only the top level volumes unless made invisible by picking. Thus the user can unwrap a branch of the geometry level by level. This has performance benefits and gives the user significant and useful control over the view. These classes show how to make a scene graph of drawn volumes, i.e., the set of volumes that have not been culled. (Normally, volumes marked invisible are culled, i.e., not drawn. Also, the user may wish to limit the number of drawn volumes for performance reasons.) The drivers also have to process non-geometry items and distinguish between transient and permanent objects as above.

3.6.1.2. Important Command Actions

To help understand how the Geant4 Visualization System works, here are a few important function invocation sequences that follow user commands. For an explanation of the commands themselves, see command guidance or the Control section of the Application Developers Guide. For a fuller explanation of the functions, see appropriate base class head files or Software Reference Manual.

- /vis/viewer/clear

```cpp
viewer->ClearView();  // Clears buffer or rewinds file.
viewer->FinishView();  // Swaps buffer (double buffer systems).
```

- /vis/viewer/flush

```cpp
//vis/viewer/refresh
//vis/viewer/update
```

- /vis/viewer/rebuild

```cpp
viewer->SetNeedKernelVisit(true);
```

- /vis/viewer/refresh
If the view is "auto-refresh", this command is also invoked after /vis/viewer/create, /vis/viewer/rebuild or a change of view parameters (/vis/viewer/set/..., etc.).

```cpp
toolkit::viewer->SetView(); // Sets camera position, etc.
toolkit::viewer->ClearView(); // Clears buffer or rewinds file.
toolkit::viewer->DrawView(); // Draws to screen or writes to file/socket.
```

- /vis/viewer/update

```cpp
toolkit::viewer->ShowView(); // Activates interactive windows or
// closes file and/or triggers post-processing.
```

- /vis/scene/notifyHandlers

For each viewer of the current scene, the equivalent of

```cpp
/vis/viewer/refresh
```

If "flush" is specified on the command line, the equivalent of

```cpp
/vis/viewer/update
```

/vis/scene/notifyHandlers is also invoked after a change of scene (/vis/scene/add/..., etc.).

### 3.6.1.3. What happens in DrawView?

This depends on the viewer. Those with their own graphical database, for example, OpenGL's display lists or Open Inventor's scene graph, do not need to re-traverse the scene unless there has been a significant change of view parameters. For example, a mere change of viewpoint requires only a change of model-view matrix whilst a change of rendering mode from wireframe to surface might require a rebuild of the graphical database. A rebuild of the run-duration (persistent) objects in the scene is called a "kernel visit"; the viewer prints "Traversing scene data...".

Note that end-of-event (transient) objects are only rebuilt at the end of an event or run, under control of the visualisation manager. Smart scene handlers keep them in separate display lists so that they can be rebuilt separately from the run-duration objects - see Section 3.6.1.6.

- **Integrated viewers with no graphical database** For example, G4OpenGLImmediateXViewer::DrawView().

  ```cpp
  NeedKernelVisit(); // Always need to visit G4 kernel.
  ProcessView();
  FinishView();
  ```

- **Integrated viewers with graphical database** For example, G4OpenGLStoredXViewer::DrawView().

  ```cpp
  KernelVisitDecision(); // Private function containing...
  if significant change of view parameters...
  NeedKernelVisit();
  ProcessView();
  FinishView();
  ```

- **File-writing viewers** For example, G4DAWNFILEViewer::DrawView().

  ```cpp
  NeedKernelVisit();
  ProcessView();
  ```
Note that viewers needing to invoke FinishView must do it in DrawView.

### 3.6.1.4. What happens in ProcessView?

ProcessView is inherited from G4VViewer:

```cpp
void G4VViewer::ProcessView() {
    // If ClearStore has been requested, e.g., if the scene has changed,
    // or if the concrete viewer has decided that it necessary to visit
    // the kernel, perhaps because the view parameters have changed
    // drastically (this should be done in the concrete viewer's
    // DrawView)...
    if (fNeedKernelVisit) {
        fSceneHandler.ProcessScene(*this);
        fNeedKernelVisit = false;
    }
}
```

### 3.6.1.5. What happens in ProcessScene?

ProcessScene is inherited from G4VSceneHandler. It causes a traversal of the run-duration models in the scene. For drivers with graphical databases, it causes a rebuild (ClearStore). Then for the run-duration models:

```cpp
fReadyForTransients = false;
BeginModeling();
for each run-duration model...
    pModel -> DescribeYourselfTo(*this);
EndModeling();
fReadyForTransients = true;
```

(A second pass is made on request -- see G4VSceneHandler::ProcessScene.) The use of fReadyForTransients is described in Section 3.6.1.6.

What happens then depends on the type of model:

- **G4AxesModel**
  - G4AxesModel::DescribeYourselfTo simply calls sceneHandler.AddPrimitive methods directly.
  ```cpp
  sceneHandler.BeginPrimitives();
  sceneHandler.AddPrimitive(x_axis); // etc.
  sceneHandler.EndPrimitives();
  ```

Most other models are like this, except for the following...

- **G4PhysicalVolumeModel**
  - The geometry is descended recursively, culling policy is enacted, and for each accepted (and possibly, clipped) solid:
    ```cpp
    sceneHandler.PreAddSolid(theAT, *pVisAttribs);
    pSol->DescribeYourselfTo(sceneHandler);
    // For example, if pSol points to a G4Box...
    |--->G4Box::DescribeYourselfTo(G4VGraphicsScene& scene){
      scene.AddSolid(*this);
    }
    sceneHandler.PostAddSolid();
    ```

The scene handler may implement the virtual function `AddSolid(const G4Box&)`, or inherit:

```cpp
void G4VSceneHandler::AddSolid(const G4Box& box) {
    RequestPrimitives(box);
}
```

RequestPrimitives converts the solid into primitives (G4Polyhedron) and invokes AddPrimitive:
Extending Toolkit Functionality

BeginPrimitives(*fpObjectTransformation);
   pPolyhedron = solid.GetPolyhedron();
   AddPrimitive(*pPolyhedron);
EndPrimitives();

The resulting default sequence for a G4PhysicalVolumeModel is shown in Figure 3.10.

DrawView();
   |--->ProcessView();
   |   |--->ProcessScene();
   |   |   |--->BeginModeling();
   |   |   |   |--->sceneHandler.PreAddSolid(theAT, *pVisAttribs);
   |   |   |   |--->pSol->DescribeYourselfTo(sceneHandler);
   |   |   |   |   |--->sceneHandler.AddSolid(*this);
   |   |   |   |   |--->RequestPrimitives(solid);
   |   |   |   |   |--->BeginPrimitives (*fpObjectTransformation);
   |   |   |   |   |--->pPolyhedron = solid.GetPolyhedron();
   |   |   |   |   |--->AddPrimitive(*pPolyhedron);
   |   |   |   |   |--->EndPrimitives();
   |   |   |   |--->sceneHandler.PostAddSolid();
   |   |   |--->sceneHandler.PostAddSolid();
   |   |--->EndModeling();

Figure 3.10. The default sequence for a G4PhysicalVolumeModel

Note the sequence of calls at the core:

sceneHandler.PreAddSolid(theAT, *pVisAttribs);
   pSol->DescribeYourselfTo(sceneHandler);
   |--->sceneHandler.AddSolid(*this);
   |--->RequestPrimitives(solid);
   |--->BeginPrimitives (*fpObjectTransformation);
   |--->pPolyhedron = solid.GetPolyhedron();
   |--->AddPrimitive(*pPolyhedron);
   |--->EndPrimitives();
sceneHandler.PostAddSolid();

is reduced to

sceneHandler.PreAddSolid(theAT, *pVisAttribs);
   pSol->DescribeYourselfTo(sceneHandler);
   |--->sceneHandler.AddSolid(*this);
sceneHandler.PostAddSolid();

if the scene handler implements its own AddSolid. Moreover, the sequence

BeginPrimitives (*fpObjectTransformation);
   AddPrimitive(*pPolyhedron);
EndPrimitives();

can be invoked without a prior PreAddSolid, etc. The flag fProcessingSolid will be false for the last case. The possibility of any or all of these three scenarios occurring, for both permanent and transient objects, affects the implementation of a scene handler if there is any attempt to build a graphical database. This is reflected in the templates XXXStored and XXXSG described in Section 3.6.1.1.1. Transients are discussed in Section 3.6.1.6.

• G4TrajectoriesModel  At end of event, the trajectory container is unpacked and, for each trajectory, sceneHandler.AddCompound called. The scene handler may implement this virtual function or inherit:
Similarly, the user may implement `DrawTrajectory` or inherit:

```cpp
void G4VTrajectory::DrawTrajectory(G4int i_mode) const {
    G4VVisManager* pVVisManager = G4VVisManager::GetConcreteInstance();
    if (0 != pVVisManager) {
        pVVisManager->DispatchToModel(*this, i_mode);
    }
}
```

Thence, the `Draw` method of the current trajectory model is invoked (see Section 3.6.2 for details on trajectory models), which in turn, invokes `Draw` methods of the visualisation manager. The resulting default sequence for a `G4TrajectoriesModel` is shown in Figure 3.11.

```cpp
DrawView();
|-->ProcessView();
 |-->ProcessScene();
 |-->BeginModeling();
 |-->pModel -> DescribeYourselfTo(*this);
 |-->AddCompound(trajectory);
 |-->trajectory.DrawTrajectory(...);
 |-->DispatchToModel(...);
 |-->model->Draw(...);
 |-->G4VisManager::Draw(...);
 |-->BeginPrimitives(objectTransform);
 |-->AddPrimitive(...);
 |-->EndPrimitives();
 |-->EndModeling();
```

**Figure 3.11.** The default sequence for a `G4PhysicalVolumeModel`.

### 3.6.1.6. Dealing with transient objects

Any visualisable object not defined in the run-duration part of a scene is treated as ``transient''. This includes trajectories, hits or anything drawn by the user through the `G4VVisManager` user-level interface (unless as part of a run-duration model implementation). A flag, `fReadyForTransients`, is maintained by the scene handler. In fact, its normal state is `true`, and only temporarily, during handling of the run-duration part of the scene, is it set to `false` -- see description of `ProcessScene`, Section 3.6.1.5.

If the driver supports a graphical database, it is smart to distinguish transient and permanent objects. In this case, every `Add` method of the scene handler must be transient-aware. In some cases, it is enough to open a graphical data base component in `BeginPrimitives`, fill it in `AddPrimitive` and close it appropriately in `EndPrimitives`. In others, initialisation is done in `BeginModeling` and consolidation in `EndModeling` -- see `G4OpenGLStoredSceneHandler`. If any `AddSolid` method is implemented, then the graphical data base component should be opened in `PreAddSolid`, protecting against double opening, for example:

```cpp
void G4XXXStoredSceneHandler::BeginPrimitives
(const G4Transform3D& objectTransformation) {
    G4VSceneHandler::BeginPrimitives(objectTransformation);
    // If thread of control has already passed through PreAddSolid,
    // avoid opening a graphical data base component again.
    if (!fProcessingSolid) {
        // for other solids.
    }
}
```

The reason for this distinction is that at end of run the user typically wants to display trajectories on a view of the detector, then, at the end of the next event 3, erase the old and see new trajectories. The visualisation manager messages the scene handler with `ClearTransientStore` just before drawing the trajectories to achieve this.

---

3 There is an option to accumulate trajectories across events and runs -- see commands `/vis/scene/endOfEventAction` and `/vis/scene/endOfRunAction`. 

---
If the driver does not have a graphical database or does not distinguish between transient and persistent objects, it must emulate `ClearTransientStore`. Typically, it must erase everything, including the detector, and re-draw the detector and other run-duration objects, ready for the transients to be added. File-writing drivers must rewind the output file. Typically:

```cpp
void G4HepRepFileSceneHandler::ClearTransientStore() {
    G4VSceneHandler::ClearTransientStore();
    // This is typically called after an update and before drawing hits
    // of the next event. To simulate the clearing of "transients"
    // (hits, etc.) the detector is redrawn...
    if (fpViewer) {
        fpViewer -> SetView();
        fpViewer -> ClearView();
        fpViewer -> DrawView();
    }
}
```

`ClearView` rewinds the output file and `DrawView` re-draws the detector, etc. (For smart drivers, `DrawView` is smart enough to know not to redraw the detector, etc., unless the view parameters have changed significantly -- see Section 3.6.1.3)

### 3.6.1.7. More about scene models

Scene models conform to the `G4VModel` abstract interface. Available models are listed and described there in varying detail. Section 3.6.1.5 describes their use in some common command actions.

In the design of a new model, care should be taken to handle the possibility that the `G4ModelingParameters` pointer is zero. Currently the only use of the modeling parameters is to communicate the culling policy. Most models, therefore, have no need for modeling parameters.

### 3.6.2. Enhanced Trajectory Drawing

#### 3.6.2.1. Creating a new trajectory model

New trajectory models must inherit from `G4VTrajectoryModel` and implement these pure virtual functions:

```cpp
virtual void Draw(const G4VTrajectory&, G4int i_mode = 0,
                   const G4bool& visible = true) const = 0;
virtual void Print(std::ostream& ostr) const = 0;
```

To use the new model directly in compiled code, simply register it with the `G4VisManager`, eg:

```cpp
G4VisManager* visManager = new G4VisExecutive;
visManager->Initialise();
   // Create custom model
MyCustomTrajectoryModel* myModel = new MyCustomTrajectoryModel("custom");
   // Configure it if necessary then register with G4VisManager
...
visManager->RegisterModel(myModel);
```

#### 3.6.2.2. Adding interactive functionality

Additional classes need to be written if the new model is to be created and configured interactively:

- **Messenger classes**

  Messengers to configure the model should inherit from `G4VModelCommand`. The concrete trajectory model type should be used for the template parameter, eg:
A number of general use templated commands are available in G4ModelCommandsT.hh.

**Factory class**

A factory class responsible for the model and associated messenger creation must also be written. The factory should inherit from G4VModelFactory. The abstract model type should be used for the template parameter, eg:

```cpp
class G4TrajectoryDrawByChargeFactory : public G4VModelFactory<G4VTrajectoryModel> {
...
};
```

The model and associated messengers should be constructed in the `Create` method. Optionally, a context object can also be created, with its own associated messengers. For example:

```cpp
ModelAndMessengers
G4TrajectoryDrawByParticleIDFactory::
  Create(const G4String& placement, const G4String& name)
  {
    // Create default context and model
    G4VisTrajContext* context = new G4VisTrajContext("default");
    G4TrajectoryDrawByParticleID* model =
      new G4TrajectoryDrawByParticleID(name, context);
    // Create messengers for default context configuration
    AddContextMsgrs(context, messengers, placement+"/*+name);
    // Create messengers for drawer
    messengers.push_back(new
      G4ModelCmdSetStringColour<G4TrajectoryDrawByParticleID>(
        model, placement));
    messengers.push_back(new
      G4ModelCmdSetDefaultColour<G4TrajectoryDrawByParticleID>(
        model, placement));
    messengers.push_back(new
      G4ModelCmdVerbose<G4TrajectoryDrawByParticleID>(
        model, placement));
    return ModelAndMessengers(model, messengers);
  }
```

The new factory must then be registered with the visualisation manager. This should be done by overriding the `G4VisManager::RegisterModelFactory` method in a subclass. See, for example, the `G4VisManager` implementation:

```cpp
G4VisExecutive::RegisterModelFactories()
{
  ...
  RegisterModelFactory(new G4TrajectoryDrawByParticleIDFactory());
}
```

### 3.6.3. Trajectory Filtering

#### 3.6.3.1. Creating a new trajectory filter model

New trajectory filters must inherit at least from `G4VFilter`. The models supplied with the Geant4 distribution inherit from `G4SmartFilter`, which implements some specialisations on top of `G4VFilter`. The models implement these pure virtual functions:
// Evaluate method implemented in subclass
virtual G4bool Evaluate(const T&) = 0;

// Print subclass configuration
virtual void Print(std::ostream& ostr) const = 0;

To use the new filter model directly in compiled code, simply register it with the G4VisManager, eg:

G4VisManager* visManager = new G4VisExecutive;
visManager->Initialise();

// Create custom model
MyCustomTrajectoryFilterModel* myModel =
    new MyCustomTrajectoryFilterModel("custom");

// Configure it if necessary then register with G4VisManager
...
visManager->RegisterModel(myModel);

### 3.6.3.2. Adding interactive functionality

Additional classes need to be written if the new model is to be created and configured interactively. The mechanism is exactly the same as that used to create enhanced trajectory drawing models and associated messengers. See the filter factories in G4TrajectoryFilterFactories for example implementations.

### 3.6.4. Other Resources

The following sections contain various information for extending other class functionalities of Geant4 visualisation:

- User's Guide for Application Developers, Chapter 8 - Visualization

[Status of this chapter]

03.12.05 "Enhanced Trajectory Drawing" added by Jane Tinsley.
03.12.05 "Creating a new visualisation driver” (from Part II) by John Allison.
09.01.06 "Creating a new visualisation driver" considerably expanded by John Allison.
20.06.06 Some sections improved or added from draft vis paper. John Allison.
Dec. 2006 Conversion from latex to Docbook version by K. Amako
